To sum up the argument, dream and waking differ in degree and form of manifestation only, not in principle and essence. Like waking consciousness, dream *reveals*, but does not *create*. The same world that surrounds the waking individual surrounds the dreaming, only the viewpoints and media of observation are changed. Observed through the operation of new structural media, the world-picture becomes visible in a new perspective—a perspective which involves the relations not only of space but also of time. For the events of a dream unfold at an incomprehensible rate, and its space, according to our notions of locality, is completely annihilated. But the workings of self-consciousness are identical. As the life-experience of an individual in his waking consciousness receives its character and value by and through his power of response to environment, so in a similar way the value of a dream depends upon the power of the Ego to respond to consciousness in its various forms of emotions, ideas, and feelings which constitute the environments of the subjective or dream-plane. Waking or dreaming, the individual is or becomes what he chooses to be at any given moment of his existence. High standards of life will generate in him a power to respond to high ideals, accompanied by a corresponding growth in his moral nature of a high and sterling character. Nor has the memory of a dream much to do with its deeper evolutionary value. For, as the recollection of important changes in the working life of an individual is not a *sine qua non* for the value of these changes as character-building forces, so the direct recollection of a dream is not a test condition, neither for its existence as such, nor for its value as ethical and moral force in our life. Dreams are concomitants to sleep, as inevitably as mental action and sensibility are to waking, but the recollection of dreams depends on the power of the mind to record the experiences of the subjective plane on the tablets of waking memory, and thus attune the corresponding cerebral structures to the scale of vibrations prevailing on the subjective or dream-plane. The somnambulist, while seldom remembering his dreams, yet by his pantomimes and soliloquies demonstrating that he is engaged on subjective planes, bears irrefutable testimony to the possibility of dreaming without the dreamer upon awakening having the slightest suspicion of having dreamed.

It would be a mistake, however, to regard all dreams as made up by sanitary admonitions, health-prescriptions, or prophesies in general. The background for ordinary dreams consists of disconnected remnants of waking life. Hence, ordinary dreams are merely undigested consciousness, being made up by longings, desires, anticipations, idle hopes, and miscarried realizations, which, occupying the mind during the day, are overtaken by sleep before having reached their fruition. On this background of disconnected odds and ends from a day of mental and moral wrestlings the images of a meaningful purpose, however, may sometimes float into view, to enter the conscious perception of the dreamer. Hence the mixture in most dreams of the sane and the insane, of truth and delusion.

On the other hand, the life lived out and assimilated in a purposeful existence becomes absorbed in the formation of character and leaves no residue to form the bizarre staging for the confused dream. And to such an individual the intuitions of dream-life, with their dazzling imagery, will introduce symbols, which, properly interpreted, may carry the significance of prevision or prophesy.

To reach this end, means to live full and absorbingly in the present. The resolute fulfilment of one's daily duty leaves no remnants for foolish dreams. Time is to events what space is to objects, and exists only where nothing has been produced to fill it. Hence, as space disappears when crowded with objects, so time will vanish when we crowd it with events. Therefore, to turn dreams into useful, intelligent, and intelligible factors we must fill our waking life with deeds and thoughts of universal usefulness, and freight the train of events with an unflinching devotion to duty and virtue.

## LENGTH OF THE ENTERON (SMALL INTESTINE).

By BYRON ROBINSON,

CHICAGO.

The enteron (small intestine) consists of the jejunum (two-fifths) and ileum (three-fifths). There is no marked division between them, nor difference in function and structure; jejunus signifying empty, and ilium flank. There is a difference in position between the two which has a fairly constant physical relation. It appears that it was J. B. Winslow, 1669-1760, a Dane, professor of anatomy in Paris, who named the proximal two-fifths of the enteron jejunum, and the distal three-fifths ileum. The enteron is the active or functional segment of the intestinal tract. It is the digestive portion, receiving the ducts (biliary and pancreatic) of the main digestive glands. Its function is peristalsis, absorption, and secretion, and its object is digestion. It is located in the area of dangerous peritonitis; in the area of absorption and not in the exudative area. The other segments of the intestinal tract are food or fecal reservoirs. The intra-abdominal pressure, which is muscular and elastic tension, compresses the enteronic loops into packets so compact that no unfilled place exists in the clefts between them. The measurements of the length of the enteron in this paper were performed chiefly in adult cadavers in the regular consecutive order of autopsies in Cook County Hospital during the past 12 years. There were some 450 males, 150 females, and 75 children. However, only 400 males and 150 females are referred to in this communication. The enteron was measured while *in situ* under similar conditions. One foot was allowed for the duodenum. The following represents the minimum, maximum, and average measurements of the length of the enteron in 550 adult subjects:

| | Min. Ft. | Max. Ft. | Aver. Ft. |
|---|---|---|---|
| 550 males and females | 10½ | 32 | 21 |
| 400 males | 11½ | 23 | 23 |
| 150 females | 10½ | 30 | 19 |

These measurements represent the enteron of man as being four feet longer than that of woman, which accords with the differences in bodily weight and stature. It also presents the average combined length of the enteron of man and woman as being 21

feet, which accords with the averages given by 30 authors during the last hundred years.

MEASUREMENTS OF THE ENTERON.

Every investigator who has studied the length of the intestinal tract has been unable to solve the problem which determines the law of its growth or dimensions. A common statement by many authors is that the enteron measures three to five times the length of the body; for example, an anatomical treatise of 1792 states that the intestines are six times the length of the body. There is no practical rule of any merit that I can discover which shows distinct relations between the length of the intestine and that of the body. Meckel announces that in man the length of the intestine is five to six times the length of the body, and in other animals three to ten times the body length. Most anatomists have been content to follow him. By reading anatomic textbooks issued during the past one hundred years, it will be noted that the two Meckels (father—1714 to 1774—and son) have been followed as authorities to a considerable extent. After Meckel's day few records of enteronic measurements were recorded until 1859, when Brinton measured 40 subjects. In 1885 Treves obtained noteworthy results by measuring the length of the intestines in 100 subjects. His reports have, for twenty years, been copied in anatomies in the English tongue. Treves states that the enteron of woman is 23 feet in length, while that of man measures 22½ feet: that is, the enteron of woman is six inches longer than that of man. This last statement I could not believe was true, for man is, in general, larger than woman, and hence it was really the announcement of Treves which induced me, some 12 years ago, to measure systematically the intestines of a series of subjects. Of the 600 subjects observed, I report 550 measurements which prove that Treve's measurements are incorrect, for woman's enteron is four feet shorter than that of man. I measured the intestines of a goodly number of animals, as the cow, pig, horse, dog, lion, tiger, seal, bird, monkey, ape, rabbit, etc., but without gaining any clues applicable to human conditions. Man's enteron stands midway between the narrow, short muscular enteron of the flesh-eater's (carnivora), and the long, wide, thin-walled enteron of the plant-eaters (herbivora). I am unable with records at command to observe any national differences of the length of the enteron. However, the clear-headed, accurate anatomist, Emil Huschke (1797-1858) asserted that the intestines of the French are shorter than those of the Germans on account of the character of the food eaten, and another author states that the Russians have longer intestines than the Germans.

It is reasonable to believe that the length of the enteron depends on the character of the food eaten during the period of the intestinal growth. However, to produce perceptible changes in the length of the enteron, ages on a definite diet would be doubtless required. The length of the enteron has no special relation in the adult to height, weight, or age. Similar testimony has been announced by anatomists for nearly 200 years. In my investigations the measurements of the enteron were made while it was *in situ*. Sufficient measurements, however, were made on the extirpated enteron by severing the mesenteron at its junction with the enteron to demonstrate that extirpated from the body it would measure from three to six feet longer than *in situ*, or while attached to the mesenteron. The conditions of the enteron are not always the same. Immediately after death the intestines are contracted, and are not as long as they are several days after death, with consequent post-mortem changes, when they relax and elongate. If the enteron contains fluid or gas, it will have a greater length than if it were evacuated and contracted. A consideration of the extensive variation in the range of length of the enteron in man should be based on childhood and youth, but especially during the first two years of extrauterine life, when we found that the minimum length of the enteron (*in situ*) was 10½ feet, while the maximum was 32 feet—a difference of 21½ feet. Twenty-one feet of intestine is an enormous addition to the usual length of the enteron, especially when it is known that the small intestine is the active or digestive portion of the intestinal tract.

Dr. Lucy Waite and I measured the enteron of quite a number of infants of different ages. We found that the enteron averages 10 feet in length at birth, but the minimum length was 6½ feet, and the maximum length was 12 feet. Referring to my notes in some 75 autopsies on children we observed: A male child, 18 months old, enteron 18 feet; male child, 8 months old, enteron 14 feet, 4 inches, etc. It was noted from our autopsies on infants that the enteron immediately after birth assumes a rapid growth in length. Treves asserts that the enteron may grow two feet a month. This is more rapid growth than our autopsies demonstrated, yet it appeared that the enteron would grow more than a foot a month immediately after birth.

The reason of the rapid growth of the enteron immediately after birth must be sought in the field of physiology—it depends on the dimensions of the enteronic nerve and vascular apparatus, and the kind of food. If an infant possesses a maximum nerve, vascular, and digestive (glandular) apparatus, by nourishing the child with coarse food, which leaves a large fecal residue, the irritation will attract a large volume of blood to the enteron, inciting peristalsis, and enhancing its assimilation and consequent growth in length. Some infants possess a maximum vascular, nerve, digestive, and muscular apparatus, hence by repeated congestion with consequent vigorous peristalsis and maximum assimila-

tion of food rapid growth in the length of the intestine may exceed the usual increase and persist beyond the usual period of development resulting in extra length of the enteron (21 feet). Extensive variation in the length of the enteron might occur in an infant from intestinal catarrh or other disease comprising digestion. Though possessed of a nominal nerve, vascular, and digestive apparatus, diseased mucosa might check assimilation, and consequent lessened length of the enteron result. Infancy and childhood is the period of maximum enteronic growth. The proper food at the proper moment in childhood tells the story of the length of the enteron. Disease of the enteronic mucosa, debilitating the nerve apparatus, compromising the vascular supply, checking peristalsis, and consequent nourishment, involves variation in the lengths of the enteron. Supposing that an infant's enteron grows at the rate of 18 inches a month, as some of the autopsies indicated, and that such an infant becomes ill or receives non-nourishing food, or has sufficient enteritis to check the growth of 18 inches a month, it would not require long to lose the growth of several feet of enteron. It is not infrequent for intestinal catarrh, or indigestion in infants to exist in various degrees for months. This supposition is not overdrawn, since it is known how much the infants of the poor are subject to changes of food fortune—now excess (indigestion), and now deficiency (starvation). All improper changes in food, excess, deficiency, or defective quality, induce compromising enteronic vascular disturbances which disturb and inhibit enteronic growth.

Enteronic growth is quite different from general bodily growth—it is more directly dependent on proper food at the proper time, and is more directly local on account of local changes in the enteronic vascular, nerve, and muscular apparatus induced by the food. Two factors must be studied in enteronic length—food and enteritis. The unfortunate vascular, peristaltic, and food fluctuations among the infants of the poor (and even the rich) tell a wondrous story as regards the length of the enteron. Perhaps a normal nerve, vascular, digestive, and muscular apparatus with similar food would produce practically a similar length of enteron. It would be interesting to study this subject in young animals for confirmation. A man with a short enteron has not such perfect powers of assimilation as one who has a long enteron, and besides a long enteron economizes food by utilizing a maximum amount of nourishment from it.

*The Position of the Enteron.*—The enteron in general occupies five locations, viz.: (*a*) some loops of the proximal end of the jejunum lie in the left hypochondrium, on the ventral surface of the left kidney; (*b*) the jejunum next crosses the vertebral column and its coils lie in the right hypochondrium on the ventral surface of the right kidney; (*c*) the enteron now recrosses the vertebral column and the loops of the distal end of the jejunum and those at the proximal end of the ileum occupy the left iliac fossa, that is, to the left of the psoas muscle; (*d*) the loops of the proximal end of the ileum occupy the central space of the abdomen between the two psoas muscles; (*e*) the loops of the distal end of the ilium occupy the lesser pelvis (especially in woman). Splanchnoptosis begins at 35 years of age and practically changes this position of the enteron by forcing more loops into the iliac fossa and lesser pelvis. As splanchnoptosis progresses the loops of the jejunum in the right hypochondrium, and to a considerable extent in the left hypochondrium, all pass distally from the relaxation of the abdominal wall and elongation of the mesenteron with distal movement of the root of the mesenteron. The psoas muscle is an important factor in the position of the enteron.

The contractions and relaxations of the psoas muscles include an extensive range, and these movements of the left psoas will form a dividing line projecting the enteronic loops either toward the left iliac fossa, or, preferably, toward the lesser pelvis (the greater space with less resistance). The largest packet of the enteron is found between the two psoas muscles. In adult life practically one-third of the enteron occupies the pelvis, and two-thirds the central part of the abdomen and the left side of the vertebral column, the relatively small number of jejunal loops occupying the right side (hypochondrium) gradually pass towards the left with increasing age and consequent splanchnoptosis. It is well to recognize the general position of the enteronic loops for diagnostic purposes in gunshot and stab wounds of the abdomen. I shot some 60 dogs to test the effect of a bullet passing through the abdomen in different directions, with special regard to position. A bullet shot through the abdomen laterally will frequently make 8 to 12 perforations in the enteron, but if the bullet passes in the ventrodorsal direction (*i.e.* with the dog standing on his hind feet), it may not make a single perforation in the enteron. To expose the most natural view of the position of the enteron secure a spare cadaver, well starved two weeks previous to death, with evacuated enteron, well frozen immediately after death. Make long crucial abdominal incisions, reflect the abdominal flaps, and the five positions of the enteron noted above may then be observed.

*The Form of the Enteron.*—The form of the enteron is that of a truncated cone, with the base at the pylorus, and the apex at the ileocecal valve. The walls of the enteron, muscular, and mucous coats, decrease in dimensions from base to apex. The enteronic muscularis diminishes in thickness and area from pylorus to cecum. The enteronic mucosa diminishes in thickness and area from pylorus to cecum. The enteronic nerve, vascular, glandular, and muscular apparatus (with digestive power) decrease distally. The enteronic power of digestion diminishes from pylorus to cecum.

*Mesenteron.*—The mesentery in 550 cases measured 7 inches both in male and female cadavers. The mesenteron is the neurovascular pedicle of the enteron. It has two borders and two surfaces. The distal border is attached to the enteron and is of the same length of the latter (average, 21 feet), the proximal border is attached obliquely to the dorsal wall of the abdomen, and is some six inches in length. The length of the mesenteron, that is, the distance from the dorsal wall to the enteron averaged seven inches in 550 adults. The mesenteron of 400 men and 150 women was practically the same in length. The enteron has two borders—one concave border, the mesenteric margin to which is attached the mesentery which conducts vessels and nerves. If this margin be destroyed by bullet or injury, gangrene of the enteron is likely to follow, because an extensive, delicate net work of nourishing vessels exists in this region. The other, the convex border, is the free border. It lies opposite to the insertion of the mesenteron. This border may be destroyed by bullet or injury, but gangrene will not follow. The form of the mesenteron is that of a truncated cone. The truncated part of the mesenteric cone, at the dorsal wall, measures six inches, the base of the cone, at the mesenteronic border of the intestine, measures 21 feet. The mesenteron is of sufficient length to allow the enteron to prolapse through the inguinal and femoral rings in 96 per cent. of subjects.

CONCLUSIONS AS TO THE LENGTH OF THE ENTERON.

1. The average length of the enteron in 400 males was 23 feet.

2. The average length of the enteron in 150 females was 19 feet.

3. Man's enteron averages 4 feet longer than that of woman.

4. The enteron increases in length most rapidly a few months subsequent to birth, when it may grow 1½ feet a month.

5. The enteron assumes its chief length in early childhood.

6. The chief variation in the length of the enteron depends on enteritis, compromising the enteronic peristalsis, absorption, and secretion, and consequently digestion, during early extrauterine life.

7. Extraordinary lengths of the enteron depend on the favorable conditions of a maximum enteronic nerve and vascular supply, with maximum assimilation continued beyond the usual period of enteronic development.

8. A subject with a maximum length of enteron possesses a stronger constitution than a subject with minimum length, as he can digest and economize more food.

9. A maximum enteronic nerve, vascular, glandular, and muscular apparatus with similar food would practically produce a similar length of enteron.

10. The foods which produce the most vigorous enteronic functions (peristalsis, absorption, and secretion) are those that leave the greatest fecal residue, which excites the enteronic muscularis into peristalsis, thus attracting more blood and inciting the enteronic mucosa to greater secretion and absorption—increasing digestion and consequently enteronic growth.

11. General and local disease influence the length of the enteron, especially during childhood, the period of life of rapid enteronic growth.

12. A child nourished with food which requires vigorous digestion, leaves a fecal residue, as cereals, would attract more blood to the enteron, enhancing its growth, than one nourished on milk only, which passes through the enteron without inducing vigorous peristalsis and leaves little residue.

13. The human enteron presents colossal differences as to length (males, 11½ feet minimum, 32 feet maximum = 20 feet, and female, 10½ feet minimum, 30 feet maximum = 19½ feet). This variation of 20 feet is almost equal to the length of an average enteron. The enteron varies over double or two and one-half times its length.

14. In adults the relation of the length of the enteron to the body length is as 7.2 to 1. There is a vast difference between the absolute and relative length of the enteron in man.

15. The enteron measured *in situ* is 3 to 6 feet less in length than when exteirpated.

16. Different diseases of the enteron may result in elongation or contraction.

For the privilege of examining the subjects I am indebted to the courtesy of Drs. Hecktoen, Crowder, Le Count, Edwards, and Evans.

100 STATE STREET.

**Russian University Professors to be Elected.**—According to the Odessa *Novosti* in the projected new university statutes the principle of election will be the basis of university life. It is proposed that candidates for chairs shall be elected by the existing professors, and that those who read treatises to qualify for professorships shall likewise be subject to the ballot of their colleagues. It is added, however, that the professors' selection will be subject to the approval of the Government, so that the appearance of liberalism is only an appearance.—*The Lancet.*

## THE POSITION OF THE BLADDER IN FIBROID OF THE UTERUS.

By J. A. SCHMITT, M.D.,

NEW YORK.

It is exceptional for the surgeon to encounter unforeseen complications while performing laparotomy for the removal of uterine myoma, because a careful examination and its verification under narcosis immediately before the operation afford him sufficient information to map out some special plan of procedure. In the clinical history we also consider the findings as to the function and position of the bladder. We decide that the position of this organ is normal, or higher or lower than normal, without going into details. If, however, after opening the abdomen, we note carefully any displacement of the bladder, if such is present, we shall find many interesting peculiarities worthy of mention and brief discussion. The bladder may be displaced laterally, may be pushed down or up, or it may be pulled up. The greatest importance attaches naturally to the last two conditions, as an elevated bladder may easily be injured in making the abdominal incison too impetuously. The term "high position" of the bladder generally applies to the elevation of the summit and body of the bladder, as demonstrated by palpation, the sound, and the existence of a fixed area of dulness above the symphysis, unchanged by catheterization. In extreme cases, the entire bladder is elevated to such an extent, that its base lies near the upper border of the pubes—a true upward displacement.

The empty bladder, to recall well-known facts, is situated in the true pelvis, behind the pubic bones; even when slightly distended, its summit may still be within the true pelvis. Of all the vesical parts, the base, with the internal urethral orifice is the least movable, because of its firm attachment to the pelvic floor. Summit and body, on the other hand, are characterized by great mobility, and loose connection with the surrounding parts. The basal portion remains fixed, while the upper portion easily distends, and rises when urine accumulates, or yields to the pressure and traction of uterine tumors. The peritoneum is reflected from the posterior surface of the abdominal wall upon the summit of the bladder at the level of the upper border of the symphysis. This reflected part is loose, and not infrequently dips into the prevesical space, thereby forming a fold. On opening the abdominal cavity, with the pelvis raised, we occasionally observe the visible part of the bladder floating. It is this part, covered by peritoneum, which displays the greatest mobility, and is first raised when the bladder distends. The anterior vesical wall is not covered by peritoneum. With increasing distention, the bladder rises, its anterior surface coming into direct contact with the abdominal wall. The loose areolar tissue of the prevesical space, continuous with the subperitoneal connective tissue, favors the free movement of the bladder and the upward displacement of the parietal peritoneum, the reflected portion of which is furthermore capable of being lifted to a considerable extent. It may happen that a myoma grows toward the pubes and bars the approach to the bladder from above, thus preventing the viscus from rising. Such imprisoned bladders produce no symptoms because of the ready lateral and downward distensibility of the organ. In women with a weakened pelvic floor, cystocele and prolapse of the anterior vaginal wall are liable to occur. Fibroid tumors situated in the lateral wall of the uterus, may displace the uterus to the opposite side; the bladder follows such lateral dislocation, but always in connection with the uterus,

and sometimes to such an extent as to occupy one side of the true pelvis.

An elevation of the bladder may be caused in a variety of ways, and depends chiefly upon the location of the tumor and the direction in which the growth develops. Any deeply seated uterine myoma may produce an elevation by pressure. Whether this pressure is exerted upon the bladder or upon the urethra, materially alters the clinical picture. In the former case, the bladder is compressed, or pushed upward and to the sides, without necessarily having its function impaired. In the latter, the pressure may cause partial or complete obstruction of the urethra and is apt to give rise to all the well-known symptoms referable to retention, viz., ischuria, dilatation with atony or hypertrophy, incontinence, cystitis, etc. Distention of the bladder may become permanent, although nowadays, when operations are more freely undertaken, an elevation of the bladder from this source seldom comes under observation. There may, however, be exceptions, when patients refuse surgical interference. I had under my care for a considerable length of time a woman suffering from a large submucous fibroid. During the process of expulsion and gradual descent, difficulty and occasional inability to urinate set in, so that the catheter had to be frequently employed. The condition became chronic; vesical catarrh and a permanent distention of the bladder established themselves. What long suffering from excessive pains and hemorrhages could not accomplish, the horror of inability to micturate brought about, namely, consent to operation.

An elevation of the base of the bladder with displacement of the whole organ upwards, so that its anterior wall comes into contact with the abdominal parietes, occurs, especially in myoma of the vaginal cervix. This pushing mechanism is easily understood and can be demonstrated experimentally by distending the rectum and bladder. High position of the bladder may also be brought about by fibroids which are situated anteriorly near the vaginal junction, or higher up, beneath the uterovesical fold of the peritoneum, where the lower posterior wall of the bladder is loosely connected with the cervix. During the process of growth, such tumors may drag the vaginal vault high up, thereby abnormally lengthening the vaginal canal. At the same time, the fundus of the bladder is drawn upwards, so that a part of it may occupy the abdominal cavity.

Fibroids developing in the anterior wall of the uterus, above the peritoneal fold, leave the position of the bladder unchanged, except in those rare cases where peritoneal adhesions exist between the bladder and uterus. The peritoneal surfaces of tumor and bladder are, as a rule, smooth, and instances in which inflammatory adhesions lead to a partial or complete obliteration of the vesicouterine cul-de-sac are seldom encountered. Those irregular distortions and dislodgements of the whole or parts of the bladder that are associated with inflammatory processes of the tumor and of the uterine adnexa, are also of rare occurrence. Of greater frequency are adhesions, supervening upon the inflammatory processes in the subserous tissue, which make the connection between tumor and bladder more intimate, and are apt, by overcoming the resistance of the strongly attached vesical fundus, to draw the bladder upward. This traction may be so extreme as to carry the internal urethral orifice up behind the upper border of the symphysis. The peritoneal fold on the floor of the vesicouterine pouch is remarkable for its great mobility, which allows its being raised for a considerable distance. In making the cross incision for detaching the bladder, we make use of this moveable peritoneal area as a line of demarkation. Tumors beneath this fold, may push the peritoneum upward and partly obliterate the vesicouterine cul-de-sac without affecting the position of the bladder. But the extent of this elevation has its limits, as above the movable zone, the peritoneum is firmly attached to the bladder and uterus. After the distensibility of the peritoneal fold has been exhausted, further traction from the tumor will be followed by elevation of the bladder.

What has so far been stated, may be summarized as follows: A tumor may cause the bladder to be: (1) pushed up by pressing on the fundus of the organ or on the urethra; or (2) drawn up by (*a*) peritoneal adhesions, (*b*) subserous adhesions, (*c*) traction on the peritoneum after the vesicouterine fold has been obliterated. Of these various agencies, I consider the subserous adhesions as the most frequent cause of an upward displacement of the bladder. It is important to bear this in mind, as an attempt to detach the bladder *with the fingers* may easily lead to an injury to this viscus.

What are the relations of the peritoneum in front of the elevated bladder? Here, also, an extraordinary mobility exists of the peritoneal bridge, which spans the space between the symphysis and the summit of the bladder, and allows the bladder to rise above the pubes. It does not matter whether the elevation is produced by an urethral obstruction or by the bladder being pushed upward from below or by being drawn up from above, the effect is always the same—the elevated bladder will lift the peritoneum and a greater or smaller part of its anterior surface, devoid of peritoneum, will come in contact with the abdominal parietes. When the prevesical peritoneal fold is lifted to an extreme degree, it finally becomes reflected upon itself, and a vesicoparietal pouch will thus be formed. I would be erroneous to believe that in extreme cases of distention a traumatic detachment of the parietal peritoneum would take place, and that the bladder would ascend between the peritoneum and the transversalis fascia. In cases of elevated bladder from uterine fibroid, we are always able, bearing this relation in mind, to introduce the finger for a variable distance into this prevesical peritoneal sac. As it is, there is always danger of injuring the bladder while making the incision, as the bladder and both layers of the peritoneum may be closely pressed by the tumor against the abdominal wall.

Those instances of elevated bladder, in which we do not find a prevesical peritoneal pouch, must be differently explained; they owe their existence to an inhibition of postfetal development and have no direct causative relation to uterine fibroids. But, as in performing laparotomies, we occasionally discover the bladder high up and immediately behind the fascia transversalis without intervening peritoneum, it may be profitable to devote a few remarks to this anatomical condition.

The bladder of the newly born infant differs from that of the adult, principally in its position and shape. The internal urethral orifice is situated near the upper border of the pubes. Three-fourths of the bladder project into the abdominal cavity and are imbedded in the loose connective tissue which extends from behind the pubes as far as the umbilicus. At the border of the upper and middle third of the space between umbilicus and symphysis, the parietal peritoneum is reflected upon the summit of the bladder, without forming a cul-de-sac, and covers its posterior surface. The still thick urachus and also the obliterated hypogastric arteries on each side of the urachus, extend from the summit of the bladder to the umbilicus. During infancy, the bladder is coni-

cal in shape, the axis of its cavity being straight. In the course of years the organ descends and assumes an ovoid or cup shaped form, its axis usually forming an angle at the junction of the posterior and inferior walls; at about the time of puberty, the empty bladder lies in the true pelvis, and the reflected peritoneum is at the level of the upper border of the symphysis pubes.

It may happen, for reasons unknown to us, that the descent of the bladder does not take place, or may only partially take place, so that an abnormally high position of the empty bladder may persist in later years. With this failure in physiological descent, there is usually associated a persistence of the conical shape. It is difficult to say how often such anomalies occur; they do not seem to give rise to any symptoms, and we are not in the habit of looking for this condition when women present themselves for gynecological treatment. It is, therefore, not strange that we are better informed about an infantile uterus, than about an infantile bladder.

Anatomists attribute the descent of the bladder principally to mechanical agencies; the pelvic cavity widens and deepens with progressive development, so that the bladder descends, while at the same time the pelvis ascends. Disturbances in the development of the pelvis may, therefore, interfere with the descent of the bladder. The different forms of contracted pelvis may consequently be associated with an infantile bladder. At all events, it is well to bear in mind the possibility of its existence when we open the abdominal cavity. In well marked cases, we discover high up and directly behind the fascia transversalis, without intervening peritoneum, a loose connective tissue, in which the conical or pear shaped bladder lies imbedded. Difficulties in recognizing this anomaly may arise in those instances, where a partial descent has taken place, but here the anatomical conditions give us sufficient clues to distinguish an infantile bladder from a bladder elevated by a uterine fibroid. In the latter, we are able to introduce a finger into the peritoneal sac in front of the bladder; in the former, the parietal peritoneum passes directly to the summit of the bladder. Furthermore, we are frequently surprised at the ease and rapidity with which the elevated bladder, when detached, resumes its former place down in the pelvis; the infantile bladder, however, remains in its bed. If, in addition, we discover a conical shape and a thickened urachus, any doubt as to the true condition is dispelled.

## DUAL GENITAL AND EXTRAGENITAL CHANCRES—CHANCRE A DISTANCE.*

By M. L. HEIDINGSFELD, M.D.,

CINCINNATI, OHIO.

Although it is commonly recognized and generally well known that, in spite of the fact that syphilis when inoculated into the human body does not long remain a local infection, and promptly assumes a general and systemic character, a secondary successful inoculation can occur for some period of time after the first inoculation has taken place. This is proportionately greater the farther the points are removed from each other on the surface of the body. Sufficient clinical instances have already been adduced amply to confirm the above observation, but they are by no means numerous, and aside from their rarity, possess sufficient clinical interest and value to merit their careful report. This is especially true in the light of our present knowledge of syphilis, particularly as to how long the infection is a local process, and in respect to the propriety of excision of the infecting chancre in order to modify or materially change the future course of the disease. It will also be of interest to note the influence of the added infection on the character of a case.

Mrs. B. I., æt. 21 years, of Tuscombia, Ala., consulted me June 19, 1905, in reference to an inflammation of the throat which had severely troubled her for almost two months. An examination revealed a large ulcer, which occupied the greater part of the right tonsil and the corresponding lateral border of the tongue. The ulcer presented a reddened, glazed appearance, and was situated upon a slightly elevated and infiltrated base, which gave palpable evidence of induration to the examining finger. The ulcer, aside from a thin coating of mucus, was clean-looking, in a state of apparent repair, and was not surrounded with much reactionary inflammation. The cervical glands on the corresponding side were enormously enlarged, to a degree producing marked deformity, but, according to the statement of the patient, had already subsided considerably in size. The cervical glands on the opposite side were perceptibly enlarged, and, according to the patient's statement, were steadily increasing in size. The patient stated that she married March 12, 1905, and four weeks later she began to experience a slight irritation, mostly in the nature of an uncomfortable sense of scratching on the affected right side of her throat. During the course of a few weeks the discomfort materially increased, and the pain became very intense, gradually subsiding the past three or four weeks, until at the present time she experienced no evident distress. Although the roseola had not as yet made its appearance, the diagnosis of an extragenital right tonsillar syphilitic chancre of a probable connubial origin was promptly established; the absence of the husband precluded the examination for confirmatory infectious plaques on the oral mucous membranes.

The patient presented herself for the second time June 20, and stated that there was some sort of a sore on her genitals which caused her some annoyance. An examination revealed a large, well-defined hard chancre situated on the crest of the right labium majus, the size of a silver quarter, with indurated base and edges. The ulcer, from which oozed just enough serous discharge faintly to stain the otherwise immaculate undergarments, was clean-looking and glazed in its appearance. The inguinal glands on the left side were markedly enlarged, insensitive to pressure, and freely movable, and those on the right side were much smaller, but otherwise similar. The patient stated that the genital lesion began about three or four weeks ago, and fully a month after the first throat manifestations asserted themselves, in the form of a small excoriated pimple, and had steadily increased in size, without causing her subjective pain and distress. On June 20 I referred the patient to a laryngologist, Dr. T. V. Fitzpatrick, who confirmed the diagnosis of tonsillar chancre.

Cases of multiple syphilitic chancres, separated from each other by considerable distance on the surface of the body, are rather infrequent. Cases of genital and extragenital chancres are even more rare, and almost unheard of in women for the reason that the genital lesion in the female sex is frequently so carefully concealed that its presence cannot be readily detected. Sherwell[13] reports the case of a wet nurse who was infected on both nipples by a child suffering from hereditary syphilis, whose mouth was full of mucous plaques. Feulard[4] re-

*Presented to the Cincinnati Academy of Medicine.

ports a chancre upon each elbow of a patient who had been treated for scabies at the Hôpital St. Louis, Paris, and assumed that the syphilitic virus gained access to the scabetic lesions from a contaminated examination table, the probability of which was strongly denied by Besnier. Pringle[12] reported a case of seven infecting lesions, all extragenital, which were situated respectively on the upper lip, forehead, left thigh, left leg, right buttock, and left nostril; they all had an apparently simultaneous development, but were of unknown origin. Petrini[10] reports a case with six extragenital chancres, all situated upon the face. Gruder[6] reports an initial chancre on the upper eye-lid, infection being derived from an hereditary syphilitic child, which was followed three weeks later by the appearance of a second or postinitial chancre on the opposed lower lid. Cases of this character are quite numerous in the literature, but cannot be properly classed with multiple infections. The postinitial lesion in such cases is not an infection, but is the result of the irritative and macerating discharges emanating from the opposed mucous or cutaneous surface. Morrow[10] reports a double chancre of that character on the upper and lower lips in a young man, and Julien[7] one of both tonsils of a young girl; the question whether these are multiple infections or the result of irritation from the opposed primarily infected surface will be clinically determined largely by their initial or postinitial development, and if postinitial they can be properly termed *Chancre irritatif*.

Few cases, to my knowledge, have been thus far reported of genital and extragenital infection in females. Ledermann[9] reports a child infected by the mother, with one lesion on the labium majus, the other in the inguinal region. Cases in males are more numerous. Dumesuil[3] reported two cases, both on the lip and the penis, to the American Medical Association in 1888. Charrier[2] reports an initial infection on the pubis, which was followed in twenty days by the appearance of the second (postinitial) chancre on the penis. Lang[8] reports three cases from personal experience, in his textbook on syphilis, one lesion on the genitals in each case, and the other on the chin, eyelid, and finger. Gaucher[5] reports an interesting case of genital and extragenital lip infection, in which the latter (postinitial) lesion manifested itself much later than the first, or initial lesion, and a considerable time before the appearance of the roseola. Audry[1] reports a chancre (postinitial) of the lip that developed fully a month after the initial lesion manifested itself on the penis, and after the latter was entirely healed, and simultaneous with the roseola.

It is commonly regarded that the severity of a syphilitic infection depends upon two essential factors—the impaired physical condition of the host, and the intensity of the infecting virus. Cases of so-called malignant syphilis, syphilis præcox, galloping syphilis, where the disease runs an unusually severe, rapid, and acute course, are strongly predisposed by general impairment from natural or intercurrent causes, and by an intense infection, as manifested by severe primary and early secondary manifestations. The latter is far more pronounced when derived from a case which is pursuing a rather severe course in a relatively early stage. It will be a matter of some interest to determine, in cases of dual infection, if the subsequent course of the disease is thereby in any way modified, and particularly if a postinitial infection from a more favorable case can exert in any manner an immunizing influence. If such would be the case, a great triumph could be readily secured in syphilitic therapy, as has already been attained by vaccination in incipient smallpox.

The interesting features of the case under consideration are: (1) Genital and extragenital infection in a female; (2) the exquisite clinical type of both primary lesions; (3) the remote disposition of the lesions on the surface of the body; (4) the long period of interval—five weeks or more between the development of the initial and postinitial lesions.

**The Local Treatment of Neuroses of the Upper Air Passages.**—Henry L. Swain in this article considers principally those diseases of the nose and nasopharynx which may be classed under the hay-fever type. He believes that a great deal may be accomplished by general care of the nose. There is nothing more helpful to facilitate healing after any simple operation in the nose, to cause diminution of the chronic hyperemia, and to restore the health of the membrane than daily cleansing. This may be done with simple decinormal saline solution. The nose should be cleansed twice a day and viscid secretions removed by use of sprays, douches, and simple stimulating powders, on the principle of pure boric acid. Many times under this régime the simple general hypertrophy, especially that of the edematous type, gradually subsides. The writer declares that simple measures, mild, continuous effects, are most essential in the treatment of these hyperesthetic conditions. Harsh measures should be used only when they are especially indicated. Care should be taken that the ciliated epithelium be not frequently destroyed, for it performs the important function of hastening the passage of the secretions from the membrane as they gather on the surface. The hay-fever patients' symptoms are due far more often to disturbances of the middle turbinate region, the anterior and upper part of the nasal septum, and in some cases the areas toward the posterior border of the latter, than all of the other parts of the nose put together. Examination will almost always reveal some pathological changes in one or more of these areas. These conditions require treatment. Anything that blocks the passage and interferes with easy breathing or easy cleansing of the nose should be removed. The cause of the particular form of irritation from which the patient suffers should also be sought for. It may be the emanation from some animal such as the cat or the horse. It may be that the occupation of the patient is irritating, like working in a tobacco shop or among the furs of animals. In certain cases if the occupation is changed the attention of the rhinologist is unnecessary. On the other hand, in certain cases, when, for example, a bent septum is straightened or hypertrophies are removed, the patient may continue his occupation with very little further trouble. It is generally best not to do radical operative work during the hay-fever period, but rather to soothe the nasal membrane by simple local treatment. Cleansing the nose several times a day with a mild alkaline solution, accompanied or followed by adrenalin chloride, for example, will tend to reduce the swelling and relieve the irritation. In bronchial asthma the nasal mucous membrane and cavities should be put into as good condition as possible.—*Yale Medical Journal.*

# MEDICAL RECORD.

*A Weekly Journal of Medicine and Surgery.*

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, August 12, 1905.

## A NEW CHANNEL OF INFECTION.

In the Address in Surgery delivered before the British Medical Association on July 27, Mr. C. J. Bond made a welcome departure from the conventional lines usually followed in such formal addresses. Instead of reviewing the progress of surgery during the past year or the past century, and recounting to his hearers what they already knew, he introduced an entirely novel theme and told his auditors of a discovery he had made, of which they had no previous knowledge, the consequences of which may be far reaching and of the highest importance. The address is published in the present issue of the MEDICAL RECORD, some of the details of the individual experiments only being omitted for the sake of economy in space, and those interested are referred to it for the facts of Mr. Bond's discovery of an upward current in the mucous canals of the body. This "ascending current" is evidently not due to muscular contractions, analogous to antiperistalsis in the intestinal canal, for it exists—intermittently perhaps—in the urethra, male and female, the common bile ducts, and even the lacteal ducts; moreover, it was found to exist in the intestine during active peristaltic movements. What the mechanism may be—whether capillary attraction along folds in the mucous membrane lining the various channels in which Mr. Bond's experiments were made, irregular contractions of the muscular fibers in the walls of those canals, or, as the author is inclined to believe, a current in the mucus lining the tubes—one can only conjecture at present.

The existence of such an ascending current, strong enough to carry with it particles of indigo, will serve to explain many cases of infection hitherto most puzzling. As the orator says, "the rapid ascent of the urethra by the nonmotile gonococcus, and the colonization of deeper portions of the tube, apart from direct extension of growth, and the absence of instrumentation or injection are thus explained. The ascending infections of the kidney by way of the ureter can also be investigated from this point of view." If pigment particles of macroscopical size can be thus transported a variable distance upward from the external opening of a mucous canal, it is conceivable that pathogenic microorganisms might be carried any distance and it would be no longer necessary to invoke the blood current or the lymph stream as the channel of infection in many cases, such as mammary abscess, or a cystitis occurring before the use of the catheter. Indeed, the significance of an upward mucous current, should its existence be confirmed by other observers, can hardly be overestimated, and one will readily agree with Mr. Bond that the presence of such a current as he describes "points to the necessity for the active recognition of the importance of all communications between the efferent canals of the body and the external world, and thus accentuates the value of personal hygiene and true cleanliness."

## SCOPOLAMINE AS AN ANESTHETIC.

TERRIER of Paris, following Schneiderlin, describes what is claimed to be a new anesthetic, and which is said when used hypodermically to produce complete insensibility lasting from nine to ten hours. The patient is thrown into a profound sleep from which he awakens as from a natural sleep, refreshed and without any idea of having been operated upon. There is not the complete relaxed muscular condition which accompanies chloroform or ether narcosis, thus offering in a large measure, material assistance to the surgeon who is better able to judge of the effect of the loss of tissue. It is declared that a patient can be aroused by shaking or when spoken to in a sharp and loud voice, but that pinching or pricking has no effect. When aroused by shaking he awakens as from a natural sleep, only to relapse without the sensation of pain. In fact he will not believe, after recovering from the anesthetic, that an operation has been performed until evidence is shown him. There is no nausea, vomiting, or distressing headache following; on the contrary, the appetite is good, food being called for, and when taken producing no disturbance whatever. This anesthetic agent is scopolamine, an alkaloid obtained from *Scopola japonica* or *Scopola carniolica*, one of the family of solanaceæ, from which atropine and other familiar alkaloids are obtained. Scopolamine has been known and used for some years as a powerful mydriatic and as a sedative, but only recently has it been known to have anesthetic properties. It is used with morphine and given in three separate hypodermic injections, the patient passing with each into deeper sleep until, after the third, he is quite insensible. The remedy is used hypodermically only, one milligram (.001) of scopolamine and one centigram (.01) of morphine in a cubic centimeter of water being injected four hours before the operation, again in two hours, and after a further interval of one hour the third or final injection is given. There is at times profuse perspiration, this effect being exactly the reverse of that from atropine. In some instances patients have seemed to be fully awake throughout the operation, often speaking and sometimes insisting upon the use of another anesthetic.

Mandragora (also called mandrake, but different from our native mandrake, podophyllum or May apple) also a member of the solanaceæ, which has similar properties, was highly esteemed by the ancients as a narcotic and hypnotic as well as an aphrodisiac and anesthetic. An alkaloid has been obtained from mandragora which is known as mandragorine; it has the formula $C_{17}H_{23}NO_3$, while that for the scopolamine is $C_{17}H_{21}NO_4$.

Frequent mention of mandragora is made by the classic writers. It was esteemed as possessing other than medicinal or toxic properties, because of the superstition that it grew best and possessed greatest worth over the buried remains of an executed criminal. The peculiar shape of the root—forked and divergent—gives it a somewhat human appearance.

The gods were supposed to make frequent use of this plant and its roots, and to place restrictions upon its use by mortals. When the plant was pulled from above the dead, groans and shrieks were heard, and those who were unfortunate enough to hear these either died or at once became insane. The great peril involved in securing so valuable a plant caused those wishing it to resort to measures that would prevent the person from hearing the fatal noises. One method was to entice a dog into the burial ground, fasten him by cords to the plant, and after sealing the ears with some substance intended to prevent the hearing of the perilous sounds, run for dear life; the dog would struggle to follow and thus tear the plant from the ground and bring it to his master, who happily escaped a miserable end. The dog, however, was a sacrifice as he was sure to perish. Shakespeare makes Juliet refer to the superstition regarding these evil sounds in "Romeo and Juliet," Act IV, Scene 3.

"So early waking—what with loathsome smells,
And shrieks like mandrakes torn out of the earth,
That living mortals, hearing them, run mad."

The similarity of mandragora to scopola is noted in that mandragora was esteemed a local anesthetic and was given in wine to those to be crucified to prevent their mental distress and pain. It is found by modern investigators to possess narcotic properties—in some instances producing hysterical excitability—in fact similar in action to our belladonna. Mandragorine, the alkaloid, resembles the mydriatics, atropine and hyoscyamine. Mandragora was also used by the ancients as an aphrodisiac.

Concerning the hypnotic or anesthetic effect of mandragora, we note in "Antony and Cleopatra," Act I, Scene 3, the following:

*Cleopatra*—Give me to drink mandragora.
*Charman*—Why, madam?
*Cleopatra*—That I might sleep out this great gap of time
My Antony is away.

This is just what is being claimed for scopolamine, an hypnotic action to last for hours.

Now note again in "Romeo and Juliet," Act IV, Scene 1, where Friar Lawrence describes the action of the contents of the vial which he gives to Juliet:

Take thou this phial, being then in bed,
And this distilled liquor drink thou off;
When presently, through all thy veins shall run
A cold and drowsy humour, for no pulse
Shall keep his native progress, but surcease;
No warmth, no breath, shall testify thou livest.
The roses in thy lips and cheeks shall fade
To paly ashes; thy eyes' windows fall,
Like death, when he shuts up the day of life;
Each part, depriv'd of supple government,
Shall, stiff and stark and cold, appear like death.
And in this borrowed likeness of shrunk death
Thou shalt continue two and forty hours,
And then wake as from a pleasant sleep.

It is impossible to say what, if any, drug or combination of drugs was used by Friar Lawrence to produce the semblance of death in Juliet. There are numerous ones which will produce prolonged sleep, but in all such cases the pulse is in evidence. There are also bodily warmth and breathing which can be determined. Opium, which was largely used in Shakespeare's time, and in fact for centuries before, could not have been alone the drug here described, for while opium pushed to complete narcosis will produce apparent death and a number of the symptoms described by the friar, there would surely be death or recovery short of two-and-forty hours. Besides, there would have been the stertorous breathing, alone sufficient to disclose life to Paris. Mandragora or possibly the plant *Scopola japonica*, from which scopolamine is procured, might have the drug used or referred to.

It is possible that scopola was used by the ancients as well as mandragora—their effects seem to be identical—and that we are rediscovering a remedy which was used centuries ago. Similar experiences are recorded, and much that we to-day believe to be modern can be traced back to ages long forgotten and unknown but for the classic writings which have been preserved.

## THE MECHANISM OF JAUNDICE.

It is not always easy—in fact it is at times very difficult—to discern the condition upon which an existing jaundice depends. Most often this consists in a catarrhal state of the mucous membrane of the biliary passages. Next in frequency as a causative factor is the presence of gallstones in the ducts, while other less common underlying states are obstruction by worms, cicatrices, or new-growths, compression by tumors or displaced organs, toxic processes, and infectious diseases, circulatory disorders and emotion. The subject is discussed in an interesting manner by Professor Gerhardt (*Münchener medizinische Wochenschrift*, May 9, 1905), in a communication presented recently before one of the German medical societies. He points out that, according to one view, bile is absorbed from the capillary biliary passages between the hepatic lobules, but histological investigation has shown that the process takes place in the intralobular bile-capillaries. There is further a difference of opinion as to whether absorption takes place through the blood-vessels or through the lymphatics.

In some cases the cause of the jaundice will be found to consist in an obvious obstruction to the flow of bile, for example by a calculus, but in a considerable number of other cases no such factor can be discovered. It has been thought by some that jaundice may result from urobilin as well as from bilirubin and biliverdin, but adequate support for such a view is wanting. In cases in which no disorder of the biliary passages can be demonstrated it seems most likely that the pigment is derived directly from the hemoglobin of the blood. Accordingly, a distinction has been attempted between hepatogenous and hematogenous jaundice. It has not, however, been shown that transformation of sufficient hemoglobin can take place in this way to result in discoloration of the entire body. In the case of jaundice of toxic origin, also, it has been found that the biliary pigment is derived from the liver, appearing together with biliary acids in the urine. Besides, this form of jaundice does not develop if the liver be excluded, and it has been attributed to polycholia or pleochromia resulting from disintegration of red blood corpuscles and the setting free of hemoglobin in the circulation. Under these circumstances also, the jaundice is in reality of hepatogenous origin. An analogous explanation is applicable to the jaundice attending hemorrhage, pneumonia, and diseases of the heart, and occurring in the newborn.

The distinction as to the origin of the condition is not without practical significance. Often there is in addition a catarrhal state of the biliary passages, and it has been thought that at times the liver cells themselves are the seat of disease. In this connection it

is probable that bacteria—and especially the bacillus coli communis—play a most important part. The utility of intestinal disinfection and elimination must therefore be obvious.

### A Filter Plant for New York.

The letter which Health Commissioner Darlington recently sent to the Mayor, urging upon him the necessity of having the water supply of New York filtered before it is distributed through the city, has excited little comment in the daily press—much less, indeed, than the exceedingly great importance of the subject would call for. The question of expense offers a fatal objection to the measure in the minds of the unthinking, and we admit that a proper filtration plant would cost money. Dr. Darlington estimates that it could be built in two years at a cost of $17,000,000, and that thereafter its maintenance would cost the city $900,000 a year, including interest on the original expenditure. In presenting this estimate he says: "This may be a large sum to pay for pure water, but a careful computation of the yearly loss in wages of those who become ill, and those who die from drinking impure water, the private and public expense of caring for the sick and burying the dead would, I believe, more than maintain a filtration plant and pay for the interest on the investment." We have not far to go for arguments in support of this contention. The situation in Philadelphia is ideal so far as the furnishing of comparative statistics goes. Part of the city is supplied with filtered water, part with untreated river water, and another part with a mixture of the two. In the entire city the average weekly morbidity from typhoid fever during the past ten weeks was 7.48 for each 100,000 population, while in wards supplied by direct pumpage from the Delaware River, the weekly average has been 26.34 for each 100,000; in wards supplied almost wholly with filtered water the average has been 2.37, and in wards supplied exclusively with filtered water 0.49. In New York City during the past six weeks, there have been 519 cases of typhoid fever reported to the Board of Mealth, and during the next six months the number will be proportionately very largely in excess of this. It needs little figuring and less imagination to convince oneself that the saving of even half of this morbidity from typhoid fever alone would be cheap at an annual expenditure of less than one million dollars.

### Asia's Possible Danger from Yellow Fever.

Sir Patrick Manson, the Director of the London School of Tropical Medicine and Medical Adviser to the British Colonial Office, passed through New York last week on his way to San Francisco, to deliver the Lane lectures before the Cooper Medical College. In a reported interview while here, he called attention to a point in connection with the Panama Canal which has been spoken of a number of times, but has received slight consideration as yet, and that is the possibility, when the canal is completed, of the introduction of yellow fever into Asia. Yellow fever is still unknown in Asia, but should it be introduced there Sir Patrick Manson said, the prevailing habits of life of the natives would make the consequences terrible. The question of the sanitation of the canal zone is, therefore, not merely a temporary problem during the building of the canal, but the welfare of the world demands that the region be rendered permanently safe and healthful. This, of course, is very true, but the danger would be comparatively slight, even if the American sanitarians neglected their duty, for the voyage of two weeks from Panama to any Asiatic port, would suffice to bring into evidence any infection contracted on the Isthmus, since the extreme period of incubation of yellow fever in five days. It is, furthermore, not likely that any ship would harbor infected mosquitos for a fortnight without their presence making itself known by new cases of fever occurring after the lapse of five days from port. In that case the ship would be known to be infected, and precautions could be taken.

## News of the Week.

**The Yellow Fever Situation in New Orleans** presents little change. The health officers seem to have the epidemic fairly well in hand, though there has been no marked falling off in the number of new cases. At the request of the city and State authorities the U. S. Public Health and Marine Hospital Service has taken charge of the situation, Dr. J. H. White being in command. The work will be prosecuted along the same general lines as before, but instead of having only one organization, the city will be divided into fifteen or twenty districts, over each of which a Marine Hospital surgeon will be placed in charge. Under him will be a force of workers for fumigation, mosquito destruction, and general sanitation work, All these men will be commissioned by Mayor Behrman as police officers, with full power to enforce the sanitary ordinances. Forty surgeons will be detailed for the work, and they will be assisted as far as possible by the men already in the employ of the Citizens' Sanitary Association. Without disparagement to the work already accomplished by the local authorities, it is a matter of congratulation that the management of the epidemic has been placed under national control. The officers of the Public Health and Marine Hospital Service are trained men, familiar with the means of fighting epidemics, and they will compel the respect and confidence of the neighboring communities which are now given over to panicky distruct of the New Orleans officials. The latter, we doubt not, would have succeeded in arresting the progress of the epidemic in time, even without the help of the Marine Hospital Service, but under Federal control the process of sanitation will be more rapid and thorough. The communities which have been enforcing a strict shotgun quarantine may have to relax a little, for they are threatened with famine, all communication with the outside world having been absolutely cut off, and the local food supplies being nearly exhausted.

**A Commission from the Liverpool School to Study Yellow Fever.**—Sir Alfred Jones, President of the Liverpool School of Tropical Medicine, has requested that Major Ronald Ross and Dr. Rupert Boyce, professor in the school, be allowed to go to New Orleans to study the disease and the measures employed in overcoming the epidemic. The two professors sail for New York on Saturday of this week.

**Steamer from Colon Quarantined.**—The British steamship *Barnton,* from Port De Paix, Hayti, for Chester, Pa., has arrived at the Delaware breakwater with fiftcen of her crew ill with what is believed to be malarial fever. The vessel was remanded to the government quarantine station at Reedy Island, Del., for fumigation and observation. The vessel had been at Colon before touching at the Haytian port and shortly after leaving the latter place the illness among the crew developed. None of the crew have been allowed to leave the vessel, and the development of the disease is being watched by the United States Marine Hospital authorities.

**Efforts at Mosquito Extermination Successful.**—Reports from various points in New Jersey and Long Island that in previous years have suffered severely from mosquitos, show that the determined campaign waged against the pests this season has been very successful. Many localities that have hitherto been extremely undesirable as summer resorts have been rendered thoroughly comfortable by the energetic drainage operations and oiling of pools that have been carried out. Still, it is said that mosquitos are few this year also in regions in which no efforts at extermination have been in force, and possibly the dryness of the summer has aided the work of the sanitarians.

**Measles in a Chicago Suburb.**—Evanston, Illinois, has an outbreak of the measles, 200 cases having been reported to the health department. More deaths have occurred from the disease, it is stated, than from scarlet fever and diphtheria. The spread of the contagion has led the health department to order a strict quarantine of all cases and all persons in the families where the cases exist are included in the order. Persons who never have had the measles are forbidden to enter any house where the disease has been found, and all such houses are placarded. Every physician in Evanston has been asked by Health Commissioner W. R. Parkes, to assist in the effort to stamp out the disease by promptly notifying the health department and taking such preventive measures as he may see fit. The Evanston branch of the Chicago Medical Society has taken the matter up, and appointed a committee consisting of Dr. Sarah Brayton, Dr. H. B. Hemenway and Dr. S. V. Balderston to assist the health department.

**The Irish Medical Graduates' Association** held its nineteenth annual meeting at Leicester on July 26, the senior foundation member present, Dr. Freer of Stonebridge, taking the chair. The principal subject of discussion was the continuance of the alleged monopoly of honorary hospital appointments in England to those holding the diplomas of two favored colleges, viz., the College of Surgeons of England and the College of Physicians of London. It was agreed to make an endeavor to get such a monopoly brought to an end, as being contrary to the principles which guided Englishmen in all their actions. One of the speakers said it was an absurd anomaly that England should proudly boast of free trade in regard to commerce while denying it with respect to medical appointments. The open door was the method of the day, but in the case of a large number of English public hospitals the door was shut to Irishmen and Scotsmen.

**Music Treatment for the Insane.**—A concert given for the inmates of the Dunning, Illinois, asylum recently demonstrated the effect of music upon these patients. Four hundred insane men and women listened quietly from the first number on the program until the conclusion. Patients who, in the wards are continuously restless, sat quiet and subdued. In the words of Dr. Podstate, general superintendent, the music was "better than barrels of medicine, and much more effective than straps or strait-jackets."

**Cholera in India.**—A despatch from Madras, dated July 31, states that a serious epidemic of cholera prevails among the refugees from the famine-stricken districts who have been crowding into the city for weeks past. Numbers of victims have been found dead or dying on the streets. The death rate is 89.7 per thousand.

**The Consumption of Tobacco** in this country is increasing, according to the internal revenue statistics for the fiscal year ending June 30. During that year tax was paid on 7,589,337,200 cigars—more than 185,000,000 in excess of the year before, and on 3,376,633,973 cigarettes—nearly 142,000,000 more than during the preceding year.

**Tuberculosis Sanatorium Not Wanted.**—Permission was recently asked of the Board of Councillors in a town in this State, for the establishment of a sanatorium for tuberculosis. Statistics were quoted to demonstrate that hospitals for the treatment of tuberculosis are not a menace to the public health. Despite the figures, when the matter was put to a vote, there was only one affirmative ballot cast, and the enlightened citizen who cast that ballot was an undertaker.

**Increase in Immigration.**—The immigration statistics for the past fiscal year have been completed and show an increase of nearly twenty per cent. over the figures of previous years. The total number of aliens admitted during the year ending June 30 was 1,027,421. In 1904 there were 812,800, and in the preceding year 857,046. The largest percentage of increase from any one country has been from Russia. The Rusisan immigration in 1903 was 136,093; in 1904 it was 145,141, to be swelled this year to 184,894. The number of deportations has also largely increased, the figure of 11,566 for the past year being about a third larger than that for 1903.

**Smallpox in Harlem.**—The first cases of smallpox to originate in New York in a number of months were discovered last week in Harlem. The patients are two colored men, brothers, who lived together, and the one who was first affected suffered so little that he continued about his work for over a week, cleaning windows and doing odd jobs in many places. Then it was discovered that his brother had smallpox and both were sent to the Kingston Avenue Hospital in Brooklyn. Daily inspections of the tenants in the block in which the men lived are being made, and will be continued for twenty-one days.

**Medical Director John C. Wise, U. S. N.,** has been given command of the naval medical school at Washington. He succeeds Medical Director Robert A. Marmion, who has been assigned to other duties.

**Homeopathic Medical Society of South Eastern Ohio.**—At the recent meeting in Zanesville, O., the following officers were elected: *President,* Dr. E. P. Cook, of Granville; *Vice-President,* Dr. Martha N. McBride, of Zanesville; *Secretary and Treasurer,* Dr. Harry E. Hunt, of Newark. Newark was selected as the place for the next meeting to be held in January.

**Willamette University** in Oregon is to have a medical school and plans have been drawn up for a building to be used for this department. It is hoped to have the exterior work finished before the beginning of winter.

**Typhoid Fever in Brooklyn.**—Within the past six weeks there have been nearly sixty cases of typhoid fever reported from one district in Brooklyn, twelve of these cases occurring in one week. In the entire city the number of cases is increasing rapidly, having risen from 47 cases and 0 deaths for the week ending July 8, to 122 cases and 13 deaths for the week ending August 5.

**The International Anatomical Congress,** which has been in session in Geneva during the past week, has accepted an invitation to meet in Boston in 1906.

**Obituary Notes.**—Dr. Robert Maitland Petrie died suddenly at his home in Jersey City, on August 3, from heart disease. Dr. Petrie was born at Libert , N. Y., in 1850. He was educated at Princeton and afterwards studied medicine at the Univer-

sity of Pennsylvania, taking his degree from that institution in 1871.

Dr. Robert F. Beattie, a Brookline physician, died in the surf at Phillipsbeach, Swampscott, on August 6. He had been in poor health for several months and in the opinion of the medical examiner death was due to disease of the heart.

Dr. Henry Hatch of Quincy, Ill., died July 24 at the age of fifty-seven years. He was a graduate of the Louisville Medical College in 1872, and of the Long Island College Hospital, Brooklyn, in 1880. He was ex-president of the Tristate Medical Society, and a member of the Mississippi Valley Medical Society, the International Academy of Railway Surgeons, the Adams County Medical Society, and the American Medical Association.

Dr. O. Wellington Archibald of St. Paul, Minn., died suddenly on July 27, at the age of sixty years. He was a native of Nova Scotia and was a graduate of the College of Physicians and Surgeons, Keokuk, Iowa, in 1871, and of the Missouri Medical College in 1873. He was formerly superintendent of the Iowa Institute for Feeble Minded and of the North Dakota Hospital for the Insane.

Dr. Isaiah White of Salt Lake City died July 23 at the age of seventy-seven years. He was a graduate of the New York University Medical College in 1855 and had practised in Salt Lake City for thirty-one years.

Dr. Louis Lynn McCabe of St. Louis died July 27 at the age of fifty-five years. He was a native of St. Louis and was graduated from the Medical Department of Washington University in that city in 1872. He was on the attending staff of Mullanphy Hospital for twenty-five years.

Dr. George Ayers Hewitt died at Cape May, N. J., on August 1, at the age of fifty-seven years. He was born at Philadelphia, and was graduated from Jefferson Medical College in the class of 1877. He engaged in the practice of his profession at Minneapolis for a time, but later returned to Philadelphia. He was a noted linguist and he did a considerable amount of literary work.

Dr. E. B. Hutcheson of Buchanan, Ga., died suddenly, July 27, at the age of eighty years. He received his degree from the Atlanta Medical College.

Dr. Francis Marion Setzler of Whitmire, S. C., died July 29, after an illness of several months' duration. He was a graduate of the Medical College of the State of South Carolina in the class of 1862.

Dr. E. G. Martin, Jr., of Glasgow, Ky., died July 21 at the age of twenty-seven years. He was a graduate of the Louisville Medical College in 1904.

Dr. John M. Edwards of Bevier, Mo., died July 31, at the age of fifty-one years. He was a graduate of the Medical Department of the University of the State of Missouri, in the class of 1883.

Dr. J. Francis Ross, sixty-two years old, died at his residence in Clarion, Pa., on July 28. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1868. In 1876 he was vice-president of the State Medical Society and later of the American Medical Association. For years Dr. Ross was assistant medical director of the Pittsburg and Western Railroad and a member of the board of pension examiners.

Dr. Robert Walter Pearce of Louisville died on July 28. He was born near Shelbyville, Ky., in 1830, and was graduated from the Medical Department of the University of Louisville in 1852. He practised for a time in Jefferson County and then returned to Louisville. He retired from active practice several years ago.

## Correspondence.

### NEW ORLEANS AND HER NEIGHBORS.

To the Editor of the Medical Record:

Sir: I was very much pleased to see the reference to yellow fever having prevailed in the past in Philadelphia and other Northern cities in your most excellent editorial headed "The New Orleans Experiment," in your issue of August 5. I have seen yellow fever transmitted to people residing in districts where the stegomyia fasciata mosquito was unknown. Hence I believe that while this variety of mosquito will transmit the disease by carrying the infection from a yellow fever patient to another person, it is only an incident, not a necessary factor, in transmitting the disease. Experience is the best teacher and the facts justify my conclusions.

During the time that I was secretary and executive officer of the Tennessee State Board of Health, it became necessary for the Mississippi Valley States to force New Orleans to observe certain rules and regulations to prevent the infection going up the river. It was forced to adopt the suggestion agreed upon by a conference of these States, and it is therefore inexcusable to find at this late day these well established rules overlooked by the Louisiana authorities, to say nothing of carelessness in not having already attempted to do the reasonable thing in reference to getting rid of mosquitos. I therefore rather approve of the action of Mississippi's strenuous governor because, if New Orleans will not keep her promises, if she continues to violate well established rules, if she lazily sleeps through the quiet times and only wakes up when forced to do so by her neighbors, I would say now in all seriousness that the surrounding States and the national government should make it so hot for Louisiana that she will not go asleep again for a half century at least. What is the use of finding the truth and then not being guided by its teaching? Why should the other States take such great risks simply because New Orleans does not keep her promises made years ago?

As to New York City and other Northern cities I would urge our health officers not to feel too secure—not to play with fate. Let them keep in mind epidemics of the past which depopulated various Northern centers, and allow no person who has not passed the limit of time to enter our ports.

C. C. Fite, M.D.

New York.

### OUR LONDON LETTER.

NEW RED CROSS—THE HEALTH CONGRESS—A FOURTH CENTENARY OF A MEDICAL BODY—FEEBLE MINDED—CONFERENCE ON EPIDEMIC SMALLPOX.

London, July 21, 1905.

A new Red Cross Society has been inaugurated under the most favorable circumstances. The step has been taken under the auspices and indeed at the instigation of their Majesties the King and Queen, who recently came to the conclusion that such a new organization was desirable. The idea is to coordinate all existing societies which are concerned with the succor of the sick and wounded in war. A council has been appointed by their Majesties under the presidency of the Queen, with Lord Rothschild as chairman.

The first meeting of this council was held on Monday at Buckingham Palace. The Queen presided and opened the proceedings with a speech. Her Majesty said it had been on her mind ever since the South African War and she became president of the Red Cross Society to try and reorganize it on a more practical basis. It was a great pleasure to her to find that the council consented to join hands with the National Aid Society founded by that distinguished soldier, the late Lord Wantage. The new society is to be based on membership and association, to be entirely voluntary and recruited from all classes throughout the Empire. It will be in touch with the War Office and Admiralty, but act wholly independent of them in time of peace, but naturally in time of war must be under military and naval control. "I therefore now appeal," said the Queen, "to all the women of the Empire to assist me in carrying out this great scheme, which is essentially a woman's work, and which is the one and only way in which we can assist our brave and gallant army and navy to perform their arduous duties in time of war."

Lord Rothschild then gave some particulars of what had been accomplished by the several societies who will now be amalgamated and the advantages that may be expected from this step. The inestimable value of the Queen's presi-

dency was naturally the first, but as his Lordship also pointed out, the new society will have the advantage that on its council will be those who have the most intimate knowledge of what soldiers and sailors require in time of war and who know to what extent and in what way the society can work in harmony with the military and naval authorities. There will also be on the council eminent physicians and surgeons who were present in the South African War and some civilians who were there also. I notice, too, there are ladies to support their Queen.

It was agreed to appoint an executive council, probably in September. Mr. Vokes, Secretary of the National Aid Society, was appointed Secretary to the new Red Cross, and the meeting closed with expressions of thanks and gratitude to the Queen for presiding.

The Fourteenth Congress of the Royal Institute of Public Health is being held this week in London. It began on Wednesday with a meeting of the delegates, numbering over a thousand, who came from all parts of the United Kingdom and from several colonies and India. The institute was founded nineteen years ago with the object of associating those engaged in teaching the various branches of preventive medicine and all others engaged or interested in the promotion of public health or the development and settlement of questions affecting the health of the community.

The representatives of municipalities appeared in their robes of office and many graduates of universities in their academic costume, so the scene presented a lively appearance.

Professor W. R. Smith, president, welcomed the delegates and thanked the London health authorities who had all joined in the preparations for the congress. The Marquis of Londonderry was then invested with the chain of office, as president for the year, and delivered his address. In it he dealt largely with the subject of education in its relations to sanitation, as was natural in the minister of the department. He could not support some of the proposals which have obtained the approval of a certain number of sanitariums, but which would import new principles into our legislation. The matter of underfed children and care of the degenerate were examples. There were parts of these problems that could not possibly be touched by legislation. The task before us is to spread that social education which taught people how to live; not merely to provide immediate necessities, but to make provident provision for the future. We could not go armed with the power of the law to impose wholesome living on everyone. In schools it was useless to lay down rules for preserving health. The fundamental instruction is rather how to put such rules in practice. His Lordship then mentioned what was being done by the education department respecting both pupils and teachers, and held that there was great hope of reducing the numbers of those who by physical and hygienic defects menaced the welfare of the nation.

A vote of thanks was accorded to the president. During the day many of the delegates visited the Health Exhibition at the Polytechnic, where some of the sections are held, the others being at King's College.

In the evening there was a fête in the Botanic Gardens, which were beautifully illuminated, and a military band provided music.

Yesterday and to-day sectional meetings occupied the time from 10 A. M. to 1 P. M. and 2 to 4 P. M. They will be resumed on Monday. The rest of the day was given to garden parties, dinner and so on. There are eight sections, viz.: Preventive medicine, municipal administration, school hygiene, engineering and building, bacteriology and chemistry, veterinary hygiene, naval and military hygiene and tropical hygiene. In all these presidential addresses are announced and papers will be read. What a plethora of hygienic instruction!

This week also the Edinburgh Royal College of Surgeons is celebrating its fourth centenary, as it traces its history back to July, 1505. Yesterday the Fellows assembled in the old Parliament House and then proceeded to St. Giles's Cathedral, where a special service was conducted. After this they were entertained at luncheon by the municipality. Then they had a commemorative meeting in the McEwan Hall of the University, Sir Patrick Heron Watson, president of the college, in the chair, supported by Lord Provosts of Edinburgh and Glasgow, Principal Turner and other members of the universities of Scotland, the Lord Justice General and other judges as well as a number of public bodies. A reception in the evening concluded a busy day.

The Edinburgh College is the oldest of our medical authorities. It was originally incorporated as a burgh craft by the Town Council, but in its long history has received various charters. By 1778 it had become a royal college, but it was not until 1851 that it attained all the privileges it enjoys and which were confirmed by the Medical Act of 1858. With sufficient time and space at one's disposal many interesting points of medical history might be given in connection with this ancient corporation.

Dr. Clifford Allbutt, giving evidence before the Commission on the Feeble-minded, said if there is any increase in the number of such persons it was only because we are doing our best to breed them. Their lives are spared, their physical condition improved and their freedom enlarged, while little or nothing is done to prevent their propagating their kind. Yet the influence of heredity is well known to physicians.

A conference on the prevention of epidemic smallpox was held at the Mansion House on Tuesday, the Lord Mayor in the chair, under the auspices of the Imperial Vaccination League. The Lord Mayor of York moved a resolution pointing out the needless suffering and waste of public money incurred, and declared he had no sympathy with the "conscientious objector." The Lord Provost of Glasgow seconded, adducing figures from that city proving the value of vaccination. Sir W. Church followed and showed that the mortality from smallpox in this country was ten times that of Germany. The Duke of Northumberland, the Mayors of Preston and Birkenhead, Mr. Brudenell Carter and Dr. Armstrong, M. O. H. of Newcastle, also spoke, and a memorial was extensively signed urging the government to adopt such legislation as had been so successful in Germany.

## Progress of Medical Science.

*Boston Medical and Surgical Journal, August* 3, 1905.

**A Case Illustrating the Local Conditions after a Suprapubic Enucleation of the Prostate.**—Arthur L. Chute reports a case interesting because it shows the conditions of the bladder and surrounding structures in a patient dying twenty-three days after the operation. The patient was 72 years old. When he came under the observation there was absolute retention due to a valve-like mass that arose from the intravesical portion of the left lobe which shut over the internal meatus. There was also lateral pressure exerted upon the prostatic urethra by a relatively small fibrous prostate. The placing of too much importance upon the obstruction of the bladder outlet and the ignoring of this element of lateral pressure, was undoubtedly a factor in making the partial suprapubic prostatectomy, the precursor of the transvesical enucleation, an unsatisfactory operation. The condition of the left ureter and kidney illustrated very strikingly the harm that may follow upon chronic retention when the bladder is infected. The rupture of a cyst in the cortex of the left kidney into the pelvis and the consequent hemorrhage showed a complication that was unique and impossible to foresee This ruptured cyst was brought about probably by a wave of extra congestion. In his paper he does not attempt to take up the whole subject of the suprapubic enucleation of the prostate, but he tries rather to call attention to the immunity which it enjoys from certain complications and to show the reasons for this immunity as illustrated by the conditions found in the patient.

**Some Observations on the Treatment of Epilepsy.**—Daniel H. Brower does not think that sufficient attention is paid to prevention of epilepsy, which he regards as a symptom, and not a disease. Neurotic children that have convulsions in infancy should receive the kind of education and medication that will insure a vigorous physical development and a well regulated mentality. Before laying the foundation for therapy every case demands the most thorough investigation, and we should bear in mind that in the pathogenesis of epilepsy we have autointoxication, increased irritability of the nervous system, deficiency of vasomotor tonus and circulatory capacity and cerebral sclerosis. These four factors must be considered with care, and the treatment applied will depend upon our findings. No epileptic can be regarded as cured until there has been at least five years' intermission in the epileptic manifestations.

*New York Medical Journal, August* 5, 1905.

**The Premature Infant.**—Dewitt H. Sherman reports the results of efforts at the Children's Hospital, Buffalo, showing what can be done with premature or weak children. He discusses the care of the premature child under the following different heads: (1) Maintenance of normal temperature. Twenty-nine premature infants were received, and of these thirteen had subnormal rectal temperatures upon admission. Of ten babies having a rectal temperature of 96° or less, all but two died. On admission, if the rectal temperature is low, and especially if there is cyanosis present, the child is placed in a warm mustard bath, with the least possible amount of handling and the gentlest artificial respiration, and remains there until the temperature is 99°. They are then treated as those entering with normal

temperatures. As they can tolerate it, the temperature of the incubator is lowered to 90°, where it remains till the child is showing steady improvement and a gain in weight. Ten babies were in such bad condition as to require hot baths and artificial respiration; nine died, five on the first day and four later. Seven babies were remarkably cyanosed, and all died. (2) Judicious feeding. They commence feeding with breast milk almost immediately, diluted with an equal part of water, to which has been added sometimes one or two per cent. of sugar of milk. In from four to eight days plain breast milk is used. They had not resorted to gavage in a single instance. The age of the child of the wet nurse should correspond to that of the infant who takes her milk. They had not used the white of egg mixture. (3) General care, including medication. Emphasis was laid upon the importance of fresh air and the proper amount of moisture. They medicated with great caution with small doses of brandy and strychnine as stimulants, and gastric antacids and digestants, and iron in the form of fresh expressed beef juice. To prevent hypostatic congestion and head deformities, the position of the child is frequently changed. No general baths are given until the child is ten to twelve weeks old, and the nutrition and general condition good. Interesting statistics were appended.

**The Significance of Sudden Severe Abdominal Pain.**—Charles S. White refers to only a few of the more common lesions requiring prompt surgical intervention. Perhaps the most frequent cause of abdominal pain is an infected appendix. It is first noted in the epigastric or umbilical region, is quite diffuse, and later becomes localized in the appendical region, associated with muscular rigidity, point tenderness, and vomiting, with or without fever. Sometimes sudden severe pain of an intense, agonizing character in the right inguinal region will be the very first symptom. Severe pain in this region may be due to an infected gall-bladder, a floating kidney, an occluded intestine, a ruptured extrauterine sac, a specific prostatitis, a pleurisy, or a specific salpingitis. In perforative appendicitis the pain is agonizing, and is followed by shock. In gangrenous appendicitis the pain is agonizing and accompanied by muscular rigidity, point tenderness, fever, rapid pulse, and anxiety. When a tubal gestation sac ruptures, sudden, agonizing pain follows, which may be diffuse, but soon becomes localized low down in the pelvis, and is persistent; there is muscular rigidity, tenderness and an anxious expression. Vomiting may be absent. If hemorrhage is severe, syncope and extreme anemia result. The severity and frequency of the paroxysms of pain in intestinal obstruction depends to a great degree upon the completeness and the suddenness of the obstruction. In intussusception the child is suddenly awakened with intermittent, colicky pains in the abdomen, the pain surpassing in severity almost every other abdominal pain to which children are subject. When a coil of intestine becomes strangulated, pain of a very severe paroxysmal character is a prominent symptom. The danger of trying to reduce a strangulated hernia by taxis is more real than apparent, and the possibility of reducing it *en masse* must never be forgotten. At best, taxis is a very dangerous and deceiving method, and should rarely, if ever, be employed. Volvulus of the small intestine causes severe, sudden and acute pain. When the sigmoid is involved the initial pain is paroxysmal, and not specially severe; gradually the pain becomes localized, persistent and distressing. When strangulation is due to bands, the onset of the pain is sudden, severe, and quickly becomes agonizing. Severe, persistent paroxysms of pain in the hypochondriac or epigastric region may be due to an incarcerated diaphragmatic hernia. In obstruction due to an enterolith, the pain is gradual, but becomes severe, and is usually associated with prostration. When a duodenojejunal hernia becomes strangulated there is sudden colicky pain in the epigastrium, which becomes agonizing In mechanical ileus the pain is at first slight, and the paroxysms not frequent; gradually the picture of complete obstruction becomes distinct. Mesenteric embolism and thrombosis do not always cause intense pain, but in by far the greater proportion of cases the onset is sudden and severe, the pain being almost always sudden, severe, and, at times, agonizing. It may be continuous or intermittent. This article is to be concluded.

*Medical News, August* 5, 1905.

**Galvanism as a Curative Agent in Nervous Diseases; the Importance of Equipment and Technique.**—William Broaddus Pritchard believes that galvanism is an agent of demonstrable value, though by no means to be indiscriminately applied. Organic lesions, with destruction of tissue, hemiplegia, destructive myelitis, and necrotic softening from any cause are seldom benefited by galvanism, and personally he has never seen any benefit in tabes from this or any other current. In active inflammatory or actively irritative central diseases it is positively contraindicated. In the nuclear palsies he had never seen any benefit from its use. It is, however, in a field of peripheral nerve diseases that galvanism occupies a field of positive and indispensable importance. To this group he adds, from experience, the fatigue psychosis, the headaches and the cerebral conditions underlying the abscessions of neurasthenia, and of simple affective melancholia. Even in this field galvanism is rarely a specific; in fact he knows of no nervous affection for which electricity, or for that matter, any other single agent is a specific. To get the best results requires a good workman and good tools. The quantity of electricity should not be guessed at. A satisfactory and complete outfit, simple in construction and management, with ample current, equipped with all necessary accessories, can be obtained at a nominal cost. The accessories mentioned are absolutely essential; the meter for accurate dosage, the rheostat for perfect control of the current and proper electrodes to localize properly your current where needed. He describes half a dozen electrodes, for the forehead, the neck, spinal, intercostal, the foot plate and for the hand, all being modifications of Erb's, and which he believes to be of distinct advantage.

**An Attempt to Adapt for Clinical Purposes, the Tests for Electric Conductivity of Urine.**—L. E. Schmidt asks how are we going to determine previous to an operation whether one kidney will suffice to attend to the necessary eliminative process after its mate is removed. All the methods so far described meet with many objections and they, therefore, tried to construct a method which was independent of the fallacious assumption of a general standard and which will permit the important discrimination between a permanently diseased kidney and a normal kidney only temporarily reduced in its elimination. They argued that the best way to test an organ would be to test its reaction and resistance toward the extraneous influences; they therefore endeavored to find out whether running a stain through the kidney might not influence the functional capacity of a normal and an abnormal kidney in a different way. The stain they selected was indigo-carmine, and as method of testing they selected for electric conductivity on account of its extreme sensibility. The order of the experiments were outlined in the following manner: First, it was necessary to find out in what way, if at all, in normal kidneys, the passage of a stain would influence the electric conductivity of the urine produced. Second, it was necessary to find out whether it would be possible to classify diseased kidneys according to the surgical question, "Can one kidney be relied upon to attend to the necessary elimination after its mate is removed?" The collection of the specimens before and after staining has to be done inside of such a short period of time that the general condition of the patient to be examined remains the same during the collection. In this way they made each kidney a standard unto itself. In order to get the basis for classifying the kidneys in a surgical sense, they discriminated between diseased kidneys that had produced heart and general symptoms and those that had so far not produced such symptoms. The first class they considered as still safe in a surgical sense; while the latter were looked upon as absolutely unreliable.

**Stricture of the Urethra; Preliminary Note on a Tunneled and Grooved Sound and a Tunneled and Grooved Catheter for Dilatation.**—Victor Cox Pedersen gives the following features of this sound: The curve is of the same radius as the standard urethral sound, but one inch shorter. This makes less leverage upon the face of the stricture and decreases the danger of injuring the filiform and of making false passages. The taper of the curve is uniform from its base to its tip and regularly includes six sizes from No. 12 F. upward. The tunnel of the sound is one-third larger in diameter than the diameter of a small filiform and is five-eights of an inch long. The groove of the sound passes along the shank three-quarters of the length thereof, thus insuring ease of testing the freedom of the filiform. The tunneled and grooved catheter alluded to in the title are designed in the same manner, namely, with a short surve of uniform taper of six sizes, a shank one inch longer than the standard, tunnels of uniform diameter, five-eights of an inch long, and grooves of uniform length, depth and width throughout the series.

*American Medicine, Aug.* 5, 1905.

**The Normal Malay and the Criminal Responsibility of Insane Malays.**—Major Charles E. Woodruff says the Malay is found to resemble some of the North American Indians, and all the cruelty so well known in our dealings with Indians has been duplicated in the Philippine wars. The intelligence of the Malays is also quite limited, and their brains are much smaller than those of Northern Europeans. As a consequence, the Malay is like a cruel child, delighting in the sufferings of others, and is naturally bloodthirsty. An epileptic murderer is described, whose sanity was questioned by reason of the cold-blooded manner

of the crime, but comparing the deed with the actions of normal Malays, the conclusion was inevitable that there was no evidence of insanity whatever. Incidentally, it is shown that the ordinary means of eliciting testimony under oath in our courts do not succeed with Malays, who have no conception of the necessity of telling the truth. Indeed, false swearing is a fine art whenever it is to the interest of the witness to conceal the truth. The jury system cannot be used because of the false conclusions at which the Malay arrives even should he have facts on which to reason. It is shown that a mistake has been made by providing no means for the trial of white men by white judges, as experience in other tropical countries has proved it to be unsafe to trust a European to native judges. Though the Malay cannot be trusted with political power, he must be compelled to obey civilized law and cease his savagery, because life and property must be made safe in every part of the world where the white man's needs take him. The Americans have already made great progress in the Philippines in restoring order, and there should be no unjust or ignorant criticism nor any clamor to give the Malay a freedom he cannot sustain nor a part in the government he cannot understand. He is to be helped and not abandoned as was the negro.

**Why Surgical Fixation of a Movable Kidney Will Not Relieve Dyspeptic and Nervous Symptoms.**—Charles D. Aaron says the study of several hundred cases in his own practice has led him to the belief that movable kidney in itself cannot produce all the dyspeptic and nervous symptoms of which patients complain, unless there is a displacement of some other organ in the abdomen. Cases in which the kidney alone is movable, are those in which there are few or no symptoms. The author's results in over 600 cases, with a properly fitting band, have proved eminently satisfactory. Before fitting a band to patients with movable kidney, the location of all the abdominal organs must be accurately made out. This is done by palpation, ausculatory percussion, transillumination, inflation, Röentgen ray, etc. A movable kidney is only pathological when it is palpable. We can therefore readily see the irrationality of producing a pathological condition by fixing a kidney that ought to be mobile. When a patient is in the dorsal decubitus position, gravity carries the kidney back to its normal position. This cannot take place when a kidney is surgically fixed, and under these circumstances there is always an abnormal condition. In cases of movable kidney, surgeons irrationally endeavor to bring about an ahnormal adhesion, and in this way induce a condition that may aggravate the symptoms they are endeavoring to relieve.

**Management of Transmissible Diseases.**—D. H. Bergey says the general prevalence of some of the transmissible diseases may be attributed to two important causes: (1) The infection of large numbers of individuals through mild and often unrecognized cases; and (2) the failure to enforce the sanitary precautions that would prevent the dissemination of infectious materials. The difficulty experienced in the satisfactory isolation of cases of transmissible disease in private houses calls for the more general treatment of these diseases in proper isolation hospitals. There is still considerable apprehension on the part of physicians and laymen with regard to the possibility of conducting hospitals for the treatment of the transmissible diseases in urban communities without danger to those living in the near vicinity. There are at least four important sources of danger from such hospitals, yet, with proper equipment and management, all of these dangers may be eliminated. They are (1) the danger of the dissemination of infectious materials through the drainage; (2) the danger of the dissemination of infectious materials by means of air currents; (3) the danger of the dissemination of infectious materials by insects or vermin; (4) the danger of the dissemination of infectious materials by the physicians, nurses, attendants, visitors, or the convalescents. Each of these dangers can be reduced to a minimum in a well-regulated isolation hospital. No one who comes in contact with the patients should be allowed to leave the hospital before taking a full antiseptic bath and making a complete change of wearing apparel.

**Hypnotic Cumulative Action as a Therapeutic Guide.**—George F. Butler discusses the principle of aggravation of symptoms from the standpoint of therapeutic indication, so far as hypnotics are concerned. Hypnotics may be roughly divided into those having cumulative action, and those destitute of this. Almost all the synthetics have cumulative action, while vegetable hypnotics, as a rule, have none. Almost all hypnotics are more or less alterative and antipyretic. The factors underlying insomnia are disturbances of metabolism, causing the circulation of toxic products which interfere with proper blood supply, and with the sleep habit by introducing an irritating factor on the monarchical vasomotor center at a time when this requires most regular rhythmic action. The cumulative effects of the hypnotics, as shown by their extreme effect hours after their first administration, indicate that this can be secured by broken doses given at intervals, so as to secure the acme of their influence during the hours after midnight, when this influence is most needed. The various alterative effects of the hypnotics serve as an indication that they will counteract the effects occasioned by the products of altered metabolism which are irritating to the monarchical vasomotor center of the medulla. The synthetics, which are more potent in these particulars, can be aided, and their injurious effects removed by the addition of vegetable hypnotics, like conium, and those derived from the solanaceæ blend, as well as certain opium derivatives.

*Journal of the American Medical Association, Aug.* 5, 1905.

**Suppurative Affections of the Head and Neck.**—According to M. I. Schamberg, the larger proportion of pyogenic affections of the face and neck, save those that occur through the skin, arise from the teeth. The throat and nose are only occasionally the seats of original infection, and persons without teeth are seldom troubled with extensive suppurative processes. Many of the tooth affections at fault are not readily detected until swelling or fistula occurs. Another class includes cases in which infection takes place in distant parts through the lymphatics, and only careful examination of the mouth reveals the source. Schamberg mentions cases in which edema of the glottis, embarrassing respiration and suppuration of the neck suggesting Ludwig's angina occurred. He thinks that in most cases of Ludwig's angina the source of infection, if sought for, would be found in the mouth. The preventive treatment of these conditions, therefore, consists in proper care of the mouth and teeth and attention to every abscess and infected focus, extracting teeth if necessary. When there is but little suppuration, abortive treatment may be tried, such as intermittent cold applications, and if the lymphatic glands of the neck are enlarged the use of the *x*-ray, which he has found a valuable adjunct in the treatment not only of this, but of other suppurative conditions, such as alveolar pyorrhea. The curative treatment consists primarily in evacuating the pus when its locality is detected. If found early enough, this can generally be done by incision within the mouth. Extraction of a tooth is justifiable when the patient's health suffers, or to avoid draining an abscess externally. It is not, however, always sufficient, and other openings may have to be made. He cautions against making large external openings, and prefers the trocar and canula to the knife. This, with curettement and the use of a small drainage tube, properly secured, and a large wet bichlorid of mercury dressing, changed daily, with syringing through the tube, will generally obliterate the cavity in a week or two, and the wound may be allowed to heal, leaving an insignificant scar.

**Tooth and Nail Corrugations.**—Excepting Hutchinson's notches, the corrugations of the teeth and nails are not much mentioned in medical literature, and G. Lenox Curtis remarks that this neglect is a mistake, and that they have a decided pathological significance. From the study of many cases, he is satisfied that the transverse lines on nails and teeth are caused by autointoxication resulting in rheumatism, and that the severer the attack the more prominent are they. Children whose mothers suffered from rheumatism during pregnancy and those that have rheumatism themselves during the period in which the enamel of the permanent teeth is developing show these corrugations. The longitudinal indentations on teeth and nails, Curtis thinks due to autointoxication from intestinal indigestion, and that white spots on the nails also indicate autointoxications. When these markings are absent, a corresponding absence of the diseases may be assumed. The nail markings have importance, owing to the fact that they are temporary, being obliterated in a month or two by the natural growth of the nail. They are, therefore, indications of recent disease.

**Eye Injuries.**—F. C. Heath reports cases of eye injuries falling under three groups, and illustrating special points in the management of these lesions. The first three cases reported are of foreign bodies in the crystalline lens, and show that, while these may remain quiet for years, they may become dangerous, and need to be kept under observation. The second group includes three cases of foreign bodies in the iris. In the first a particle of steel had remained imbedded twenty-two years without giving trouble. It then began to produce symptoms, and at last had to be removed on account of signs of sympathetic irritation, twenty-seven years after the first injury. The iris is evidently very tolerant of foreign bodies, but these, nevertheless, are possible sources of irritation, and should be kept under close observation. The third group of cases involved wounds in or near the ciliary region. They illustrate the fact that danger lies more in the position than the size of the wound. In two of the cases the wounds were extensive, but the ciliary body escaped injury, though very closely approached, while

in the remaining case the wound, though very minute, involved the ciliary region and necessitated the ultimate enucleation of the eye. It showed the great danger of prolapse of the iris, however small, in this region, and the author thinks that it is only in exceptional cases of prolapse and in those seen rather late, that he would be inclined to resort to prompt operation, whether near the ciliary region or well within the corneal margin.

**The Matas Operation for Aneurysm.**—J. A. Danna reports two cases of fusiform aneurysm rupturing into the surrounding tissue, and treated by him by Matas' method of suturing the leading openings within the aneurysmal sac. In neither case was the sac obliterated, but drainage was employed, and the results were satisfactory. In one of his cases to have sutured together the walls of the cavity would have required a fourteen-inch incision. He thinks it is better in such cases to close the incision partly and to drain, allowing the cavity to fill up by granulation, instead of closing it by suture, as is done in the unruptured cases.

**Inhalation of Nitric Acid Fumes.**—J. N. Hall and C. E. Cooper report the disablement of eighteen firemen, four of whom died, caused by the inhalation of nitric acid fumes. Two of the deaths occurred on the second day as the direct results of the inhalation, the other two after several weeks as the result of relapse. Eleven of the survivors still have symptoms referable to the accident. The pathology, in the opinion of the authors of the paper, was as follows: The irritating fumes of the nitric acid and the combinations formed with the chemicals employed in putting out the fire, which were deeply inhaled during the violent respiratory efforts of the physical exertion, caused a mild coagulation necrosis of the mucous membrane of the air passages and the alveoli, and in the two patients who died early there was produced promptly a severe bronchopneumonia. In those dying later the partially healed and susceptible areas were readily excited, by exposure to cold, into an especially severe bronchopneumonia which rapidly proved fatal. The excessive cyanosis observed in the severer cases is credited largely to changes produced in the hemoglobin of the blood, interfering with its oxygen-carrying capacity. The treatment generally adopted was, they believe, that of an ordinary severe bronchopneumonia. The authors think that, at present, stimulation, the use of oxygen when indicated, atropia for the edematous exudation, vigorous counter irritation, with eliminative and supportive measures, offer the most hope in the primary attack. After recovery from this, they urge stoppage of work, avoidance of all exposure, and residence for some months in a warm, equable climate suited for feeble cases suffering from chronic bronchitis. The most important thing of all is the avoidance of anything that may bring about a relapse. In view of the lessened pulmonary resistance, it is advisable to keep clear of any possible infection of tuberculosis.

*The Lancet, July 29, 1905.*

**Temporary Fixation of Testis to Thigh.**—A series of 25 cases operated on for undescended testicle is reported by C. B. Keetley. The first step is to free the cord and testis. The main incision he makes over the inguinal canal and the external ring, two other incisions being made, in the majority of the cases, one about 1¼ inches long at the bottom of the scrotum and the other of the same size in the upper and inner part of the thigh adjacent to the scrotal incision. The testicle and cord having been thoroughly freed from everything but the fibrous and muscular bands forming the gubernaculum, this then is divided as far away as possible from the testicle. A pair of forceps is passed through the hole in the scrotum and the gubernaculum is seized and pulled right through the scrotum till it can be seen through the hole in the skin of the scrotum. The tunica vaginalis should also be pulled down into the scrotum. The posterior borders of the apertures in the skin of the scrotum and thigh are then united with sutures left long. The gubernaculum testis is sutured with strong catgut to the fascia lata; then the original suture is used to complete the union of the skin opening in the scrotum and thigh to one another. The hernia usually present is treated as the surgeon thinks best. The testis is left attached to the thigh for five months as a rule. Do not fasten the testis too close to the fascia lata. The testis usually remains permanently in the scrotum but near its root. Some of these testes grow when brought down in the scrotum. The presence of hernia was noticed in ten out of the twenty-five cases.

**Treatment of Acute Summer Diarrhea in Infants.**—J. A. Coutts says that when these cases are seen early a purgative should be given and all milk withheld. He prefers calomel to castor oil. There is no remedy which has any influence over the disease as an entity and the main treatment is that of the symptoms with careful regulation of the diet when food is resumed. He treats the vomiting by washing out the stomach with warm water or a weak solution of bicarbonate of sodium. After this he administers a tenth of a grain of cocaine or less in a teaspoonful of iced water. These measures may be supplemented with safety by a mustard poultice over the epigastrium and the administration of a mixture of carbonate of bismuth and bicarbonate of sodium, along with a quarter of a minim of dilute hydrocyanic acid. During the time of abstention from food the vomiting is relieved by frequent teaspoonfuls of hot water. The number of drugs that have been advocated for the treatment of diarrhea is legion and their very number is proof of their general inadequacy. When the motions are particularly offensive he found benefit in giving a mixture containing a minim each of glycerin, carbolic acid, and tincture of iodine. For the ordinary run of cases he found nothing more useful than half grains each of gray powder and Dover's powder, given every four hours, alternately with bismuth mixture mentioned above. When the infant is in a state of collapse when first seen a mustard bath is of value. The return of sweating is a valuable sign. Any irritating or infectious material should be washed from the bowel; otherwise this might increase the existing toxemia. In states of extreme exhaustion from any cause a large warm injection will act as a sedative and often induce sleep when other means have failed. The milk should be withheld for twelve hours and on its resumption it should be sterilised or pasteurised. Pancreatised or peptonised milk are apt to cause looseness of the bowels. The commonest forms of substitution for cow's milk in the early stages are veal or mutton broth, albumin water, and raw meat juice. They should not be continued for more than twenty-four or forty-eight hours. A castor oil purge and the withholding of food for a few hours will promptly cure most cases and prove a safeguard against the acute diseases.

**A Case of Pulmonary Embolus with some Peculiar Features, Occurring Shortly After Normal Labor.**—A woman, aged 25 years, a healthy multipara, pregnant at full term, with second stage well advanced, is reported by R. J. Waugh. A healthy, full term male baby, weighing 8 pounds, was born. He immediately expressed the placenta and left the patient in a comfortable condition. One hour later he was called and then found the patient sitting propped up in bed gasping for breath. The dyspnea was extreme. The pulse was rapid, compressible and extremely irregular. Cardiac dulness had extended an inch beyond the right sternal margin. No breath sounds were audible in the upper lobe of the left lung, but in their place many fine moist râles could be heard. From the commencement of the attack a colorless frothy liquid, at times stained with hemoglobin, was coughed up in considerable quantities. As the more alarming symptoms seemed to be due to an acute engorgement of the right ventricle a small venesection was made, ten ounces of blood being withdrawn, and five minims of solution of strychnine, together with twenty-minims of pure ether, were given hypodermically, weak brandy and water being ordered by the mouth. The next morning she was quietly resting, and she seemed to be none the worse for her experience. From this time on the puerperium was uneventful. He believes that the condition was caused by an embolus which had been carried away and arrested in the pulmonary circulation, and this embolus must have been composed of air rather than dislodged blood clots.

**Iodoform and Mercury in the Treatment of Tuberculous Peritonitis.**—David Sandler records a case of successful treatment of tuberculous peritonitis with iodoform and mercury. The patient was a female child about 6 years of age who had been bedridden for several months. The parents regarded the case as hopeless. The patient appeared to be as a skeleton, both upper and lower limbs being merely skin and bones. Her face had the monkey-like expression. The lips were covered with sordes. The head was studded with large boils. The abdomen was much distended, hard to touch, and pigmented. Foul bedsores were encountered. The morning temperature was subnormal. The case was evidently one of chronic tuberculous peritonitis. He prescribed powders consisting each of half a grain of mercury with chalk and half a grain of iodoform, one powder to be taken in milk three times daily. He also directed equal parts of ointment of mercury and ointment of iodoform to be rubbed over the whole abdomen. Under this treatment the child gradually improved.

*Berliner klinische Wochenschrift, July 17, 1905.*

**The Bactericidal Properties of Typhoid Serum.**—Elischer and Kentzler, as the result of an extensive series of experiments, have come to the conclusion that attempts to treat typhoid fever by the introduction into the patient's body of the serum of immunized animals or of convalescent patients is not likely to be productive of satisfactory results. It appears that bacteriolysis in the body of the typhoid fever patient is hindered by the organism itself in two ways. There is in the first place an over-production of amboceptors through which the complements are held back from the bacteria, and in the second place the serum develops an activity

similar to that of anticomplementation, and distinguishable from this only by the fact that its active agent is destroyed by a temperature of 56° C. The damaging effect of the bacteria is due to their endotoxins, but these become active only after they have been liberated and enabled to attack the body through the lysis of the bacterial bodies. Bactericidal serum therapy therefore offers a prospect of satisfactory results only when the number of bacteria is so small that the amount of endotoxin their destruction would set free would be too minute to be dangerous. Under the opposite conditions the endotoxin liberated would bring on the disease and if present in considerable amount would cause death. As long as the patient's body is protecting the bacteria it is also guarding itself against the action of the endotoxins, against which it is unable to produce antitoxins; therefore every measure intended to hasten the slow destruction of the bacteria by the body would be detrimental instead of beneficial.

*Münchener medizinische Wochenschrift, July* 18, 1905.

**New Observations on the Etiology of Syphilis.**—Siegel continues his report on the nature of syphilis in a communication describing the results obtained by inoculating rabbits and monkeys. He has succeeded in securing a large number of positive inoculations both on rabbits and guinea pigs, the primary lesions being followed by secondary eruptions. Although similar results have been obtained in some instances by former experimenters, the author's observations are distinctive on account of their extent, almost fifty rabbits having been used, and owing to the fact that in all the animals after a certain period of incubation had elapsed flagellated organisms could be demonstrated in the blood and tissue juices. These are regarded by Siegel as the causative agents of the disease. In order to prove the syphilitic nature of the disease induced in the rabbits reinoculations were made on twelve monkeys. These all exhibited both primary and secondary lesions, the former appearing from ten to thirty days after the infection. That these manifestations are not due to the effect of the introduction of foreign albumin is shown by the fact that inoculations from one monkey to another were equally successful. Inasmuch as in every animal at the height of the disease the cytorrhyctes flagellates described by the author could be found in large numbers as the only parasites both in the blood of the living subjects and in the tissues and smears at autopsies, he concludes that it is justifiable to assume that the cytorrhyctes luis is the cause of syphilis.

**The Treatment of Hypertrophy of the Prostate with Roentgen Rays.**—Moszkowicz and Stegman report very gratifying results in the treatment of prostatic hypertrophy by means of the Röntgen rays. Apparently the prostate is especially susceptible to the action of the rays and the authors suggest that the parenchyma may easily be destroyed in this way, owing to the large amount of lecithin it contains. Six cases are reported, all of the patients having suffered for some time from urinary obstruction sufficiently great to make spontaneous micturition impossible. The rays were applied by introducing a Kelly proctoscope up to the gland and covering the buttocks and perineum with a protective screen of lead. The reflector of the tube was then placed so as to throw the rays against the desired part. In no instance were more than three treatments given, as the response of the gland was so remarkably prompt that in several instances the power of voluntary urination was restored after only two radiations. The objective changes in the organ are very striking, as it diminishes markedly in size and becomes much softer to the touch. Nearly all the patients at first complain of increased desire to urinate and of a feeling of fulness in the perineum. In some cases an existing cystitis was temporarily aggravated, and in one case an epididymitis of short duration was excited, but all of these symptoms promptly subsided. As soon as it is obtainable the authors propose to treat the intravesical portion of the gland with a tube of radium introduced on a suitable instrument.

**A Test for Diacetic Acid in the Urine.**—Lindemann has devised an improvement on Riegler's test for diacetic acid in the urine which he believes is also superior to the older tests, such as Gerhardt's. Riegler's test is performed by adding to 15 c.c. of urine 2 c.c. of ten per cent iodic acid solution, and then shaking with 2 3 c.c. of chloroform. If diacetic acid is present the iodine is not liberated and the chloroform remains colorless, but if this constituent is absent the chloroform takes up the iodine and is colored red. Lindermann has modified the test as follows: 10 c.c. of the urine are acidified with five drops of thirty per cent. acetic acid and five drops of Lugol's solution are added. After shaking, 2 c.c. of chloroform are added. The chloroform remains colorless only in the presence of diacetic acid. The amount of the latter if present may be estimated by noting the quantity of Lugol's solution that may be added before the excess of iodine begins to color the chloroform. The test is more sensitive than the Gerhardt reaction and is not interfered with by such substances as the salicylates, or by the addition of small amounts of formalin to the urine as a preservative.

*Deutsche medizinische Wochenschrift, July* 20, 1905.

**The Treatment of Hypertrophy of the Prostate.**—Oberländer, in discussing this subject, says that of the operative methods prostatectomy is the one that will probably hold the field in the future. The sexual operations have been practically discarded and Bottini's operation is uncertain and dangerous. Radical surgical intervention is, however, rarely necessary and the practitioner will usually succeed in controlling his cases by the judicious use of the catheter and of vesical irrigations. In the earlier stages of the condition it is very important to counteract the tendency to constipation that is always present by the constant use of different laxatives, and to reduce the amount of fluid taken. Rectal medication with iodoform or ichthyol may be of service if the gland is tender, as well as prolonged warm sitz baths, one to three times a day followed by rest in bed. Massage of the prostrate and cold rectal irrigations are also to be recommended. Sooner or later catheterization must be begun to remove the residual urine, and for this purpose the author advises especially the elastic instruments with the Mercier curve. It is a mistake to catheterize too infrequently, and bladder irrigations should also be begun both to cure any existing cystitis and as a prophylactic. In cases of retention in which catheterization is difficult injections of eucain and adrenalin facilitate the operation. The patient can soon be educated to catheterize and wash out his own bladder, but the greatest pains are necessary in order to impress him with the necessity for asepsis. The irrigator is not suitable for the patient to use in washing out the bladder, as the tendency is to admit more than 60-80 grams of fluid at a time, which may prove injurious, and only the syringe should be employed.

**A Primary, Non-gonorrheal Urethritis With Influenza Bacilli.**—Cohn believes that many of the cases of so-called primary urethritis of unknown etiology may be due to the influenza bacillus and describes an illustrative instance. The patient was a man who, several days after coitus, developed a urethral discharge in which no gonococci could be found though numerous other bacteria were present. On making cultures two organisms were obtained, one a plump capsulated bacillus and the other the influenza bacillus; later on a slight epididymitis and cystitis developed. The patient remained under observation seven weeks without any apparent improvement in spite of constant treatment. Although the presence of the other capsulated bacillus complicates the problem somewhat, the author believes that the affection was a true influenzal urethritis, basing his conclusion on the fact that the influenza bacilli were so numerous and that an epidemic of the disease broke out shortly afterward.

**A Simple and Rapid Method for Staining the Spirochæta Pallida.**—Oppenheim and Sachs describe their technique as follows: The smears are dried in the air and then without previous fixation are flooded with an alcoholic solution of carbol-gentian violet. This is made by adding 10 c.c. of concentrated alcoholic gentian violet solution to 100 c.c. of five per cent watery carbolic acid solution. The preparation is warmed until it steams and then is carefully washed with water and dried with blotting paper. If there are many red cells in the smear these may be partially decolorized or washed away, but this does not affect the staining of the spirochetae. These appear distinctly and are blue in color, and correspond in morphology to Schaudinn's description, though they are somewhat wider, owing to the fact that as alcohol is not used the protoplasm has not been contracted by fixation. If the smears are first fixed with alcohol, fairly good but less clear preparations are obtained. The method offers the advantages of rendering it easily possible to find the plainly stained organisms and of being rapid and simple. No special training is necessary either to make the preparations or to find the organisms, so that the method may be used for diagnostic purposes.

*French and Italian Journals.*

**Apyretic Fatal Puerperal Infection.**—Paul Guéniot reports his observation of a woman suffering from puerperal infection of the most severe type following placental retention after abortion. The patient died without showing any elevation of temperature and with scarcely any increase in the frequency of the pulse rate. The case was so unusual that it was suggested that death might not be due to infection but possibly to mercurial poisoning. Chemical analysis of the viscera, however, did not reveal a trace of mercury, hence the case is considered one of infection of abnormal type.—*La Presse Médicale*, July 12, 1905.

**Pneumonia with Relapse.**—Antony recently had the opportunity of observing a case of recurrent pneumonia. The patient was a man twenty-nine years old, who, after a chill developed pneumonia at the base of the right lung. The lesions which at first were accentuated in the posterior region of the lung, about the seventh day extended to the anterior region. On the next day the first crisis occurred, accompanied by distinct polyuria. Eight days later there occurred a fresh attack of the disease at the base of the left lung with a slight elevation of temperature. On the fourth day a crisis accompanied by polyuria took place. During three days the patient voided two and a half liters of urine. The temperature became normal, and convalescence was established on the twenty-first day from the onset of the disease.—*La Tribune Médicale*, July 8, 1905.

**The Administration of Chloroform by Means of a Flannel Compress.**—G. Cochet states that for twenty years he has administered chloroform by means of a simple flannel compress. He calls attention to the necessity of using flannel of medium thickness. Material too thin will fall over the mouth and nose of the patient at each respiration. A "swallow's nest" mask is useful to support thin flannel. Material too thick will not allow a sufficient quantity of air and will retain too much of the chloroform vapor. If the mask is not used the compress may be formed into a sort of dome which is held over the mouth and nose of the patient by means of the hand. With the palm of the hand the patient's eyes are kept closed while the nostrils are closed by means of the thumb and index finger in order to make the patient breathe through the mouth. It has been said that the nasal mucosa is especially sensitive to chloroform vapor and that the vapor should not be allowed to come in contact with it until narcosis has been attained. At this stage, the mucosa having lost either all or nearly all sensitiveness does not further react to chloroform. The writer then emphasizes the importance of gaining the confidence of the patient. He should be told that a docile patient will lose consciousness very quickly and easily. The compress should then be quietly applied. After closing the nostrils, the patient should be told to breathe through the mouth. From ten to fifteen inspirations should be made through the flannel without dropping on any more chloroform. The patient should be told that the odor of chloroform is not unpleasant. The anesthetist should make use of suggestion as far as he is able to do so.—*Le Nord Médical*, July 15, 1905.

**Congenital Amputation of the Fore-Arm.**—M. Hirigoyen reports this interesting case. The mother was a young primipara twenty-one years old. She had worked as a chambermaid. There was absolutely nothing of importance in either family or personal history. The pregnancy had been normal and the labor spotaneous and normal. There was rather a larger quantity of amniotic liquid than usual. The only malformation was that of the left fore-arm; this member was about one-quarter of the normal length. The stump had a conical ending in which was found a rudiment of the radius and ulna tipped by a rounded eminence consisting of cartilage. There was no trace of amniotic adhesions. The patient denied having had any maternal impression during pregnancy which could have had any relation to the deformity. The writer believes that this is a case of true amputation, but he searched in vain for the amputated part of the arm.—*Journal de Médecine de Bordeaux*, July 16, 1905.

**Resistance to Dislocation of the Atlas and Axis.**—Arrigo Tamassia contends that a dislocation of the atlas upon the axis is a very rare occurrence from violence other than that of hanging. To support this view he has conducted experiments upon the human skeleton, from which muscles and ligaments had not been removed, exerting great violence in the directions from which they could come from various accidents, in order to determine whether luxation could be artificially produced. Dislocation can occur by flexion forward, or to one side of the head or upper cervical vertebræ, or by rotation more or less transversely. The ligaments are immensely strong and will resist almost any amount of force that can be exerted. At the same time the compact muscles aid in this resistance. The author concludes that though dislocation may sometimes occur between the atlas and axis, there are grave doubts whether it can occur from head injuries, unless there exist pathological conditions of the ligaments that lessen their normal strength. Fracture of these upper vertebræ is as difficult to produce as dislocation, but supposing this to take place, death must inevitably result as a consequence of the injuries sustained by the brain and cord.—*Gazzetta Medica Lombarda*, July 10, 1905.

**Passage of Agglutinins and Antitoxins of Tuberculosis into Milk and their Absorption by the Gastrointestinal Tube.**—F. Figari has shown by experiments on rabbits that the agglutinins and antitoxins developed by animals inoculated with tuberculosis appear in the milk of nursing animals, and that these are absorbed by the gastrointestinal canal of animals fed on this milk. Such milk prevented the infection of the animals taking it by injection of tuberculous material, while control animals receiving the same injections, but not fed on immunized milk, succumbed to tuberculous lesions. He then extended his researches to two children, feeding them on immunized milk, and showed that the antitoxins were absorbed by their gastrointestinal canals, as was shown by the agglutinating power of their blood serum; at the same time the body weight was increased and the general condition was improved by the treatment.—*La Riforma Medica*, July 8, 1905.

**Treatment of Erysipelas with the Serum of Convalescents from the Disease.**—Luigi Fornaca took the opportunity afforded by a severe epidemic of erysipelas, occurring at Turin, to treat a number of patients by injections of the blood serum from patients of the epidemic who had already reached the stage of convalescence, with a view to utilizing the antitoxins developed in their blood to counteract the infection in new cases. The affection was on the face, with a tendency to spread beyond it. He gives us these conclusions: (1) The injection of such serum exerts a favorable effect on the patient, rather on the general symptoms, without lessening the local manifestations. The temperature is especially modified by it. (2) The serum does not possess bactericidal properties toward the streptococci, nor does it diminish their virulence. (3) The streptococcus can be isolated from the blood serum and from the urine when there is albuminuria. (4) Normal blood serum has no effect on the disease.—*Il Policlinico*, July, 1905.

---

**The Causes and Treatment of Baldness.**—Henry Waldo declares that there is still some difference of opinion as to the cause of thinning of the hair. Unna, Sabouraud, and others would lead us to look on all forms of baldness as parasitic in origin. The writer thinks that there is no doubt that alopecix areata is sometimes contracted from domestic animals, especially the dog and cat. Parker declares that alopecia is due to autointoxication with some substance derived from the lungs owing to decomposition of organic material normally present in respired air when this air is retained in the air vesicles. Preventative measures are the most satisfactory. The seborrheic scalp may appear quite healthy to the ordinary observer, and yet there may be very marked funnel-shaped depressions around the hair follicles which are filled with fat. Ordinary soap is an effective disinfectant. If it is superfatted it causes very little dryness of the hair. If seborrhea is well marked, black soap is better, and if combined with spirits of wine and a little thymol it is an excellent remedy. The writer believes that the scalp of both men and women should be washed with soap and water at least once a week, and especially after each visit to the barber. It is well to induce an abundant blood supply to the scalp by moving it upon the skull in different directions with the towel every morning. The linings of the hat should be clean, and the hat should not interfere with the circulation or innervation of the scalp. When there is any tendency to seborrhea it should be treated with a microbicide. Hair is nearly always ready to grow if the microbe and its immediate consequences are removed.—*Bristol Medico-Chirurgical Journal.*

**Treatment of Ulcers of the Cornea.**—S. B. Muncaster thinks that most ulcers of the cornea treated at the beginning can be cured with only a slight cicatrix. Treatment varies with the stage of the ulcer. The cause of ulcers must also be considered; if they result from a foreign body or growth on the lids, this should be removed at once. In cases of corneal ulcers of the conjunctiva resulting from inflammation, caustics should be used. While the ulcer is in progress zinc solutions, on account of the irritation which they cause, do more harm than good. In cases in which there is secretion, the writer uses argyrol, applying it from half an hour to three hours. With most patients he uses 25 per cent., 120 grains to the ounce. This has no irritating effect. In some cases boracic acid, from ten to fifteen grains to the ounce, is all that is needed, if the ulcers are not infected. Sulphate of atropin and homatropin are important drugs in the treatment of progressive ulcers. Bandages applied in a light and firm manner are important in most ulcers. Dark glasses may be used instead on young children. As a rule, hot applications to the eyes are beneficial in the case of corneal ulcers. If destruction of the cornea is threatened, the writer uses tincture of iodine; it acts as an antiseptic and germicide, and does not generally leave a scar. Preventive treatment of the mother is most important when opthalmia neonatorum is feared. The writer advocates the use of argyrol in the child's eyes when this disease is suspected. In the case of traumatic ulcers great care should be taken to remove all foreign matter. Early treatment of an infected eye is most important.—*Washington Medical Annals.*

# Book Reviews.

Atonia Gastrica. (Abdominal Relaxation.) By Achilles Rose, M.D., and Robert Coleman Kemp, M.D. New York and London: Funk & Wagnalls Company, 1905.

In this volume are considered the diagnosis, symptomatology, treatment and etiology of abdominal relaxation. Dr. Kemp writes a special chapter on the methods of examination and their relative values, and gives many helpful points in mapping out the stomach. The main portion of the work deals with the adhesive plaster abdominal belt which Dr. Rose originated, and which he clearly proves to be a distinct advance in the means of supporting the abdominal viscera. Plates illustrate the simple and effective method and his selected histories prove its manifold usefulness. There is also a chapter on floating kidney as a closely allied condition.

Not only can the reader obtain new knowledge on medical subjects, but also many points on the nomenclature of diseases to which the profession gives but too scant attention.

Practical Problems of Diet and Nutrition. By Max Einhorn, M.D., Professor of Medicine in the New York Postgraduate Medical School and Hospital, and Visiting Physician to the German Hospital, New York. New York: William Wood and Company, 1905.

The author has collected several papers, and now issues them in the more permanent form of a monograph. In them he discusses the proper methods of eating, the different methods applicable to various disorders, and last, but not least, points out the error of over-dieting and the distinct advantage of a sufficient nutrition. In the final chapter he gives valuable hints about increasing and diminishing bodily weight.

Les Médecins au Théatre de l'antiquité au dix-septième siècle. Par le Dr. Witkowski. Paris: A. Maloine, 1905.

The French excel in preparing the sort of literary dessert exemplified by the present volume. Written by a German, a volume on this subject would perhaps gain in thoroughness, but it would certainly lose in sprightliness of presentation; while coming from an English pen it would probably be deficient in both characteristics. The period covered was not one in which the possibilities for broad allusions afforded by the work of the medical man were likely to be overlooked by the playwright, and accordingly the doctor or apothecary was usually introduced as a welcome variant on the conventional buffoon and made to exhibit himself in a more undignified light for the vulgar delectation of the herd. The author's running commentary on the astonishingly large number of excerpts from plays he has collected is both amusing and interesting from a critical standpoint.

Dermatologische Heilmittel. Zweite verbesserte Auflage. Würzburg: A. Stuber's Verlag (C. Kabitzsch), 1905.

In this second edition the formulæ and new drugs have been added to, while the text in general has been amplified. Many useful skin therapy hints can be found.

Les Moustiques. Histoire Naturelle et Médicale. Par Raphael Blanchard, Professeur a la Faculté de Médecine de Paris; Membre de l'Académie de Médecine. Paris: F. R. de Rudeval, 1905.

At the outset Dr. Blanchard declares that his work is primarily intended for the medical man, and that he does not offer any original classification. Nevertheless, almost half the book is taken up by descriptions of species, genera, and other details of classification, mostly from Theobald or other authors, and with many of the illustrations borrowed from Howard. As to this part of the book, it is compilation pure and simple and, while the author is unquestionably correct in his statement that a knowledge of species is necessary for satisfactory scientific work, it is perhaps doubtful whether so heavy a burden of systematic matter does not discourage the physician the more, as not over one or two per cent. of the species are in the least interesting from the medical standpoint.

The chapters on life history are up to the date of the writing, and are also mostly compilation. It is a commentary on the rapid advances made during the year or two last past, that some of the facts most important in the practical control of mosquitos are not included, and are, apparently, unknown to the author.

Chapter V, "The Mosquito as a Pathogenic Agent," and Chapter VI, "General Prophylaxis," are the most interesting and important parts of the work, and an excellent summary is given of what is known on the subject. All the known pathogenic organisms found in mosquitos are figured, and the life cycle of each is fully described, so far as known. A very useful feature is the description of methods of preparing the suspicious blood for study, and of dissecting mosquitos believed to contain malarial or other noxious organisms.

Altogether we have a useful, if not strikingly original work, which can be profitably consulted by the student and, on some points, by the general practitioner as well.

Les Processus Généraux. Tome II. Hypertrophies, Régénérations, Tumeurs, Pathologie de la Circulation sanguine, Pathologie du Sang, Pathologie de la Lymphe et de la Circulation lymphatique, Inflammation, Hyperthermie, Fièvre. Par A. Chantemesse, Professor à la Faculté de Médecine de l'Université de Paris, Membre de l'Académie de Médicine; et W. W. Podwyssotsky, Doyen de la Faculté Impériale de Médecine d'Odessa, Professeur de Pathologie générale à la même Faculté. Paris: Masson et Cie., 1905.

The first volume of this work appeared in 1901, and was duly noticed in the Medical Record of September 28, of that year. Now the second (and final) installment is at hand, and students of pathology are to be congratulated on having in a complete form this valuable work of Chantemesse and Podwyssotsky. This second volume is on the same general plan as the first, and consists of six parts; the first part deals with the general subject of hypertrophy, including hyperplasia and tumors, with a special section on the parasitic theory of the origin of tumors. The pathology of the circulation of the blood is next taken up, with chapters on hyperemia, ischemia, hemorrhage, thrombosis, embolism, and infarction. The next part is on the pathology of the blood, and contains chapters on plethora, anemia, oligemia, toxicity of serum, cytotoxins, antibodies, etc., and pathological changes occurring in both the red and white cells. The fourth part is concerned with the pathology of the lymph and the lymphatic circulation. Part five deals exhaustively with the important subject of inflammation; and the volume concludes with a discussion on the pathology and etiology of fevers and other disturbances involving the body temperature. The illustrations are very fine, and many of them are printed in colors. At the end of each section is a copious bibliography, which adds to the value of the work; but we regret that so useful a book should be issued without an index.

A Treatise on Plague. Dealing with the historical, epidemiological, clinical, therapeutic, and preventive aspects of the disease. By W. J. Simpson, M.D., Aberd., F.R.C.P. Lond., D.P.H. Camb. Professor of Hygiene, King's College, London; Lecturer on Tropical Hygiene, London School of Tropical Medicine; formerly Health Officer, Calcutta; Medical Adviser to the Government of Cape Colony, during the outbreak of plague in 1901; Commissioner for the Colonial Office to inquire into the causes of the continuance of plague in Hong-Kong. Cambridge: The University Press; New York, The Macmillan Company, 1905.

This comprehensive treatise on the plague is divided into four parts. The first, consisting of three chapters, deals with the history and distribution of plague. The second, in eight chapters, discusses the epidemiology of plague, the nature of the infection, the different views regarding the etiology of pandemics and epidemics of plague, the variations in the virulence of plague epidemics, conditions fostering the endemicity and epidemicity, diffusion and modes of dissemination. Part three treats of plague in the individual, and its five chapters go thoroughly into questions of morbid anatomy and pathology, channels of infection, clinical features, diagnosis, prognosis, and treatment. The fourth part is concerned with measures for the prevention and suppression of plague, the method which the author considers the most efficacious being the Clayton method of fumigation with the oxides of sulphur. The last chapter of the book recapitulates the facts regarding plague that are known and established; the author also enumerates the main lines on which further inquiry is needed. This separation of the known and acknowledged from that which is unknown or only conjectured is one of the characteristics of the book. The work throughout bears the mark of a master hand, and to all who are interested in the subject of plague, whether practitioners, bacteriologists, sanitarians, health officers, or students of the history of medicine, the book will be welcome as an authoritative exposition of an important subject.

Maternitas. A Book Concerning the Care of the Prospective Mother and Her Child. By Charles E. Paddock, M.D., Professor of Obstetrics, Chicago Post-Graduate Medical School; Assistant Clinical Professor of Obstetrics, Rush Medical College. Chicago: Cloyd J. Head & Co., 1905.

This is a most practical little book. Every subject touched upon is presented in a very simple and helpful manner. The first five chapters are devoted to the care of the "Mother," while the "Baby" is the text for the second part. The hygiene of pregnancy, convalescence from confinement, care of the baby and diseases and injuries are some of the topics treated. The book has a good index.

# Society Reports.

## BRITISH MEDICAL ASSOCIATION.

*Seventy-third Annual Meeting, Held at Leicester, July 25, 26, 27, and 28, 1905.*

(Special Report to the MEDICAL RECORD.)

GENERAL SESSIONS.

*First Day—Monday, July 24.*

The first general meeting was opened on Monday, when Dr. William Collier, F. R. C. P., occupied the chair. Only the adoption of the minutes was carried and the meeting adjourned till Tuesday.

*Second Day—Tuesday, July 25.*

**Address of the Retiring President.**—Dr. William Collier, the retiring president, in his farewell address briefly reviewed the principal events which had taken place in connection with the association during the past year. First he remarked that he would like to call attention to the fact that the help of the association had been asked through the branches and the divisions in aid of a very excellent association which had recently been started under the most favorable auspices, viz., The National League for the Physical Education and Improvement of the People of Great Britain. He was perfectly certain of the fact that they would be in agreement in stating that the physique of many classes of the nation was such as to leave a wide margin for improvement. Therefore he was sure when this league put forward its scheme and asked the British Medical Association to help it that help would be very readily given. He might remind them that the general health of the nation owed vastly more to the medical profession than to any other section of the community. There was another point he wished to refer to and that was the future of the society. During the year the work of the council had been increased to an enormous extent, so much so that of the four quarterly meetings three had had to be adjourned and further meetings held. Under these circumstances he appealed to the various branches and divisions and to the representative meeting to take care that only questions of first rate importance were sent to the council for discussion.

Perhaps his most pleasant duty during his year of office was to inform the chairman of the council that it was unanimously decided to award him the gold medal of the association. He thanked the members and officials of the association for their courtesy, and introduced to them—if an introduction were needed—the new president, Mr. Franklin, senior surgeon of the Leicester Infirmary. Mr. Franklin was well known throughout the midland counties, and before the week was out it was certain he would be well known in all parts of Great Britain. To his mind, Mr. Franklin had attained that period of age where all the qualities which went to the making of a good president had reached their high water level. He trusted that when Mr. Franklin's year of office closed he would be able to look upon it as one of the most pleasant years in his existence, and receive, as he (the speaker) had, expressions of good will from all parts of the Empire.

Dr. Collier then retired, and Mr. Franklin on taking the chair was warmly applauded. He thanked the association for the honor they had done him.

Dr. ANDREW CLARK moved a vote of thanks to Dr. Collier for his past services, and his election as vice-president of the association for life.

Dr. LATIMER seconded, and the proposal was carried with acclamation.

Dr. E. MARKHAM SKERRITT moved that the statement of account be received and adopted. The total excess of assets over liabilities, he said, amounted to £101,397. Their income had increased by £2,283 during the past year, but at the same time their expenditure had increased by a greater amount, viz., £2,778. If they made allowance for the amount that was charged to alterations last year, the increase of expenditure was £3,397, so that they had to recognize that, although there had been a great increase in income, there had also been a serious increase in expenditure.

Mr. KINSEY of Bedford seconded, and the proposition was carried.

Dr. MCMANUS of London moved that Dr. H. Radcliffe Crocker be elected honorary treasurer of the association.

Dr. VALANCE of Norwich seconded, and this was agreed to unanimously.

Dr. MACDONALD of Taunton moved a vote of thanks to Dr. Edward Markham Skerritt for his services as treasurer, and also that he be elected vice-president of the association for life.

This was agreed to, and Dr. Skerritt replied, saying that he would always do what he could to serve the interests of the association.

The meeting subsequently voted £300 to the office staff superannuation fund.

There was a brilliant scene in the Royal Opera House on Tuesday night when the meeting was resumed. The house was full, and the president was accompanied on the stage by a large number of distinguished medical men and others.

The Mayor of Leicester, Mr. HILTON, gave a very hearty welcome, on behalf of the inhabitants of the town, to the British Medical Association. It was their first visit to Leicester, but that was not Leicester's fault; and he thought, with others, that the visit had been too long delayed. The community rejoiced in the rapid and continuous advance in the science of surgery and medicine, and sincerely hoped that the deliberations of the association would be conducive to their best interests and usefulness.

Dr. ASHLEY V. CLARKE, senior local secretary, on behalf of the Midland branch, presented the president with a badge of office, consisting of the arms of Leicester on a golden star, with the inscription, "President B. M. A., 1905."

The guests and colonial visitors were then received by the president. Among them were Drs. Charles O'Reilly, Brefney R. O'Reilly and J. H. Cameron of Toronto, and C. N. Camac and E. A. Boyne of New York.

Then followed the presentation of two gold medals of the association—one to Sir Constantine Holman and another to Dr. Andrew Clark. The president, in making the presentation, spoke highly of Sir Constantine Holman's work at Epsom College, and of Dr. Clark's valuable services to the association.

Both gentlemen briefly returned thanks.

The president said he regretted that Mr. W. H. Power, chief medical officer of the local Government Board, was not present, as it deprived him (the president) of the pleasure of presenting to him the Stewart prize.

**President's Address.**—Mr. GEORGE COOPER FRANKLIN of Leicester then delivered his presidential address. After welcoming the members of the association to the ancient town of Leicester, the president went on to give a short history of this most interesting English town. The earliest story connected with Leicester was that of King Lear, who reigned over the land for sixty years, eight centuries before the Christian era, and was buried there with his daughter Cordelia. A village of the ancient Britons existed here before the time of the Roman occupation, and was called by them Camp Ratæ, from the ancient name of Rath, signifying a clear space. The invasion of the Saxons followed the departure of the Romans, about the middle of the fifth century, and the town now became Legraceastre, or camp on the river Ligger or Leir, now Soar. In 658 a bishop's palace and cathedral stood there, and the town was important enough to have a mint. Then came the Norman conquest, when the town was utterly destroyed. It was, however, rebuilt, and when the Assembly of Barons took place in 1201 the name of Simon de Montfort, Earl

of Leicester, was closely connected with this beginning of the English parliament. Several religious houses and hospitals were later founded here, among them Trinity Hospital in 1330, which was rebuilt in 1902. The Leicester Infirmary was opened in 1766, Dr. Watts urging the public to further the interests of the people in this much-needed charity. He told them that the poor were neglected, and that, as a natural result, their offspring were unhealthy and weak, to the great detriment of the nation. Leicester had had several distinguished physicians. Gulston was a learned man, a good classic, and had considerable practice. He endowed a lecture course, the lectures of which have been delivered yearly since 1639. Chesiden was a noted surgeon and anatomist. He invented a high and later a low operation for stone in the bladder, which he brought to so great perfection that it had hardly been improved upon up to the present day. He executed it with great rapidity and skill, first performing it in 1727. He was beyond dispute one of the greatest of British surgeons. Halford was physician to a succession of kings and queens of England, and was a practical physician of the highest order. Richardson was a sanitary reformer; spent much time in investigating drugs capable of producing anesthesia, and was an advocate of total abstinence from alcohol, which he regarded as a powerful drug. Thomas Paget also came from Leicester.

The president then passed to the regulation of medical education by the State. The Apothecaries Act of 1722 was the first act to legalize medical practice, medical men being then called apothecaries. It permitted the inspection of all drugs in shops, and the destruction of those unfit for use. It also appointed a board of ten examiners to license persons to dispense medicines. The act of 1815 prevented all persons not properly qualified from practicing as apothecaries, and empowered the Court of Examiners to grant certificates to persons twenty-one years of age who had served an apprenticeship of five years. There was a penalty for practicing without a certificate attached. The Medical Act of 1858 established a Council of Medical Education and Registration of the United Kingdom, which had since established preliminary education. The great defect was the separate registration of medical and surgical men, so that some practiced who were not thoroughly qualified in all branches. The Government bill of 1878 was a great improvement, as it included both classes of attainments, and the celebrated Medical Act of 1886 made it necessary for every man to qualify completely. This act also conferred representation in the Council on the great body of the profession. In instruction in medicine and surgery good work was done, but obstetrics, gynecology, and clinical instruction were very slightly represented. The president believed that medical education was still weak in preliminary education, in obstetric practice, and in the administration of anesthetics. To-day a student must be sixteen years of age, and must pass the matriculation examination of the London University. He then spends some three years on biology, chemistry, physics, and practical pharmacy, and has only three years in which to study all the purely medical subjects; and the number of lectures and other work he must pass through is perfectly appalling. The orator was a firm advocate of a classical preliminary training, if possible a university course, for the medical student. The discipline as well as the knowledge of classical languages was invaluable. The student should also have more practical instruction in obstetrics. Another department of medicine in which he should be thoroughly instructed was the administration of anesthetics. The medical education of the future should go less into minute histology and physiology. There should be more specialism of the right kind, as in insanity, sanitary science, etc., and less in some other lines. Specialism should not be such as to produce a narrower type of man. The last suggestion offered by the president was that all medical men should strengthen the cause of the profession by becoming members of the British Medical Association, so rendering that body more powerful to secure the best legislation for the maintenance of the public health.

*Third Day—Wednesday, July 26.*

**Next Meeting in Toronto.**—The first business of this session was to settle the place of meeting for 1906. The president announced that the council had received a deputation from Toronto, Canada, that morning, who, on behalf of the Toronto Branch, had given a hearty invitation to the association, and the council had decided to accept it. The meeting confirmed the acceptance. Subject to the nomination of the Toronto branch, the appointment of the president-elect was left in the hands of the council.

**Address in Medicine.**—Dr. Henry Maudsley of London then delivered the Address in Medicine, taking as his subject, "Medicine, Present and Prospective." He desired, he said, to indicate in a general way how the horizon of the medical profession widened day by day, and how its expectations of usefulness to mankind increased. The right of present glorification belonged rather to surgery, with its asepsis and its many improved operations, than to medicine. One phase that the author deplored was the tendency to invent long hybrid words to represent simple operations and symptoms, which concealed rather than revealed the real meaning. The future work of medicine would be to prevent and to stop the beginnings of disease, and to prevent functional disorder from lapsing into fixed disease. The first end of preventive medicine, and one that was being pursued with enthusiasm was the prevention of attacks from without; the second, which was being neglected, was to obviate the predispositions to disease which lay within the body itself. For the adoption of measures to ward off disease, the medical man was not given fair opportunities by the public, who summoned him after they became sick, instead of calling him beforehand to instruct them how to avoid sickness. What was needed was a full and exact study of radically different types of constitution and of their respective qualities and disease tendencies. Such inquiries would further the contraction of healthy marriages, or obviate the danger from such inheritances as insanity and epilepsy, perhaps teaching us how to modify them so as to produce a healthy variation of type, thus neutralizing their bad effects. The manner of the infection by cancer, its settling into the tissues without producing fever, indicated that it was the result rather of awakening to activity of the silent memories of ancestral germinal growth, than of the presence of a microbe. The question was here suggested, whether in the marriage of those having certain disease tendencies a new disease ever arose. The orator thought that probably there were no new diseases, but that we learned better to recognize old ones.

In the work of fortifying the body to resist inroads of disease, the simplest means were the best—pure air, clean and proper food, regular and adapted exercise were the measures to give inward strength and to keep the body sound and supple. To this we must add the culture of a well-disciplined mind. Its healthful exercise must be beneficial, while corroding passions and unruly affections hurt body as well as mind. A clear conception of the body as a complex reflex mechanism and an exact knowledge of its reflexes, or the sympathies of its parts, would be profitable. The present position of medicine regarding tuberculosis showed a wise recognition of the necessity of fortifying the body inwardly to resist outward enemies. The bacillus we should have always with us; nor could we prevent its entrance with our food; no true protective serum had been found to prevent its depredations. The true method of prevention was to fortify the body so that we could defy the ravages of the pathogenic agent. The bacillus must perish from inanition for want of a suitable human soil for its growth.

Another question for future medicine was whether we might not be able to eliminate the predisposing influence of heredity, by heredity meaning the poor constitutional soil which invited the inroads of the bacillus. One who had recovered from tuberculosis might still transmit to the off-

spring a constitutional delicacy, and we might question whether it was really best for the race at large to save the patient to transmit a poor heredity to his descendants. To the conception of the body as a complex reflex mechanism we must add the other conception of the body as a vital laboratory within which the most complex chemical changes took place in the organs and tissues. Concentrated within the cell body were subtle and intense forces, continuously and quietly working, which might elaborate a whole series of poisons. The excreted bodies were all poisonous; the toxic products of waste of muscle all passed into the circulation; the proteid molecule suffered decomposition, producing other poisons; the enzymes and ferments were liable to toxic mischances; in its normal state, the intestinal canal contained many possibilities of poison production; more good could be done by regulating life so as to prevent the formation of all these poisons than by attempts at chemical antidotes in the form of medicines.

Besides all these, it was imperative to consider the special poisons produced by all the pathogenic microbes. The virus of syphilis, years after the infection, produced tabes or general paralysis as a result probably of its injurious effect on the stability of the nerve molecule, which became apparent when the system was weakened by abuse of function of various kinds. The discoveries of microbial toxins promised us scientific therapeutics which should bring about scientific precision in the administration of medicines. The rapid progress of chemical research had reached the very confines of life, forecasting the ultimate analysis of the subtle physicochemical processes which represented the vital force. Advances in physics and chemistry tended to prove that vital processes rested on physical and chemical processes as a basis. We had learned that the atom was not a simple thing. Full and exact knowledge of radial energy might lead to undreamed-of success in the way of radiotherapy.

All divisions of science might gradually be effaced, even that which metaphysics had fixed between bodily and mental life. Between material energy and consciousness there was a gulf, yet the mind worked in every function of the body; there were other means of expression than mere words; subtle motions of look and gesture, gait and attitude, might play the same part as speech; no purposive movement could ever be made but as the outward discharge of mind incorporate in a fit structure. There was a subtle transfer of energy between minds, which led us to believe that two brains might be so attuned in sympathy as to transmit and receive impressions without the mediation of the senses, as the wireless telegraph receives messages over space. There should be a more advanced and methodical use of the resources of mind to cure bodily disease. This should not be left to charlatans and scientists so called; few drugs were more helpful than hope, few more deadly than despair. In conclusion, the speaker said it was a sobering second thought that the mischief done through mental bad breeding did not end with the individual life. In the moral, as well as in the physical, world the present was the product of the past and the determinant of the future. Moral deterioration was surely transmitted to the children. If mankind was to be perfected, according to Descartes, the means of perfection were to be sought in the medical sciences. Dr. Maudsley said that he could not doubt that a positive science of human nature, as it gradually emerged into form, would make it ever more and more plain that, by operation of natural law in the process of organic evolution, sound thought, good moral feeling, and devotion to a high ideal were the solid foundation of health and wealth of mind in individuals, in families, and through families in nations; that there was, indeed, a measure of scientific truth in the saying of the Hebrew seer, who, looking on the generations of old, declared that those who sowed upon the furrows of unrighteousness should reap them sevenfold.

*Fourth Day—Thursday, July 27.*

**The Temperance League Breakfast.**—Thursday's proceedings began with the thirty-sixth annual breakfast given by the National Temperance League to the association. The Dean of Hereford (Dr. Leigh) presided, and said he hoped that before long the inculcation of temperance in their schools would be universal. Dr. Harry Campbell said there was no body of men so capable of helping the cause of temperance as the doctors.

**Address on Surgery.**—Mr. C. J. Bond, F.R.C.S., of Leicester, delivered this address at the general meeting on Thursday, taking as his subject, "Ascending Currents in Mucous Canals and Gland Ducts, and Their Influence on Infection; a Study in Surgical Pathology." (See page 246.)

**The Annual Dinner** was held in the evening, when the president occupied the chair, and there was a large attendance. The Bishop of Nottingham proposed the toast, "The Imperial Forces," and Fleet-Surgeon Thomas and Surgeon-General Spencer responded. Mr. M. C. Buszard, K.C., proposed "The British Medical Association," and Dr. Langley Browne, chairman of the Council, responded. Dr. F. M. Pope of Leicester proposed "The Mayor and Corporation of Leicester." The Mayor responded. The Archdeacon of Leicester proposed "The President and Members of the Local Committee," and the last toast was "The Guests."

*Fifth Day—Friday, July 28.*

**The Popular Lecture.**—Dr. William Stirling, professor of physiology and dean of the faculty of medicine in the Victoria University of Manchester, addressed a large audience at the Opera House on the subject of "Fatigue and Repose." He said that the organs of the body acted and reacted one upon the other. Mental fatigue caused bodily fatigue, and vice versa. After a hard day's work one was not only tired in body, but in spirit as well; while overwork of the brain, especially in children, made itself evident in bodily fatigue, listlessness, and, it might be, headache. Doctors were continually warning the public about the dangers of eye strain; the senses of touch and taste and smell became affected by fatigue. Memory was also affected, and after much strain the brain required not only prolonged rest to restore vigorous mental activity, but something more, such as change and recreation. In children insufficient sleep was practically overwork. Much depended on the condition of the nerve cells. These were most active between 10 and 11 o'clock in the morning, and therefore these hours should be set apart for the study of the lessons which caused most brain fatigue. The Germans had a proverb that the morning hours had gold in the mouth. In schools much could be done by change of study. Mathematics should be followed by a quite different subject, such as drawing, while drawing and writing, which both put a strain on the eyes, should never follow one another.

The orator continued that we might take a little wider view. What did the quick lunch of the age mean? It meant over-stimulation of the digestive organs, and the business man who took this hurried meal day after day would soon begin to feel dyspeptic. He called it indigestion, and said he had a touch of liver, but would soon be well. So he would if he would act rationally and gave his digestive organs some rest. Glands, like muscles, required rest; even the tear glands of some lachrymose persons ought to be given a rest occasionally. Many people gave the kidneys far too much work to do.

Proceeding, the lecturer asked how it was that the wonderful mechanism of the body, "the harp of a thousand strings," was kept in tune so long. The secret was to be found in rhythm. The heart and the diaphragm beat and contracted rhythmically. The heart rested, or, rather, was not in action three-fifths of the time. The act of expiration was chiefly a mechanical action; the act of inspiration was a muscular act, and so the diaphragm rested, too. What was sleep but a quiescent period so far as outward manifestation was concerned, when the nerve cells rested and gained fresh energy? The brain cells should have a spring cleaning every twenty-four hours. It had been found that the homing pigeon could fly enormous distances without

fatigue—or, at least, with only that fatigue which could be overcome by twenty-four hours' rest. The pigeon had thus overcome the question of fatigue, probably not only by removing so much waste matter, but by the production of some antibody which neutralized fatigue. Plutarch said that rest was the sweet source of labor. But in addition to sleep the true rest of many a weary brain was change of occupation. For many, something approaching manual labor in the open air was best. Change of scene was beneficial; the magic of change had an effect in many cases that could not be found in the panacea of the alchemist. Change was indeed the essence of life—change and rest together. There was great wisdom in Solomon's words: "Be not righteous over much, nor make thyself over wise; why shouldst thou destroy thyself?"

**The Entertainments** this year were very numerous and very successful. One or two may be specified:

By invitation of Alderman Wood, J.P., chairman of the Leicester Infirmary board of governors, and Mrs. Wood, about 1,500 of the visitors were entertained on the grounds of the Leicester Infirmary on Wednesday.

In the evening Dr. Pope and the members of the Midland Branch gave a reception at the Museum buildings.

On Thursday afternoon Mr. and Mrs. Maurice Levy entertained about 500 guests at a garden party at Humberstone Hall, and later Mrs. Franklin and the ladies' committee gave an entertainment in the Grand Hotel.

**The Church Service** in connection with the association was held at St. Martin's Church on Tuesday, when there was a large attendance. Dr. Gore, Bishop of Birmingham, was the preacher, and said that if a minister of the Gospel of Christ was still summoned to speak to a congress of the medical profession it must be because they still recognized that man's nature was compounded of body and of spirit to serve a spiritual purpose; and that his nature required to be healed morally and spiritually as well as physically. Man's nature was created to co-operate with the divine will and law, and they had no mandate from biology or science to deny the reality of moral freedom. The church had been said to be a failure; the cause of that was found in the social and physical condition of the vast majority of the nation. He wanted the church to develop sanitation and social science, and he urged that there should be co-operation between the clergy and the medical profession.

---

SECTION OF MEDICINE.

*First Day—Wednesday, July 26.*

**Discussion on the Treatment of Sleeplessness and Pain.**—Sir T. LANDER BRUNTON, in opening this discussion, first referred to the physiology of the living cell, and the living nerve cell in particular, with special allusion to sleep. In sleep there was probably a break in the continuity of the pseudopodia of the cells of the cerebrum and those of the cells by which the organism was brought into relation with the outer world—cells situated possibly in the basal ganglia. The means by which this interruption was brought about was probably the accumulation of waste products in the sphere of the individual cells. Reference was made to the probable formation of stimulating alkaloids during sleep. The influence of the cerebral circulation on sleep was also discussed, particularly in regard to the natural contraction of the arteries during sleep, and the influence of rigid arteries or excessive cardiac action, in tending to prevent sleep. The rôle of irritants applied to the periphery in preventing sleep was also referred to. In the treatment of insomnia it was necessary to consider remedies bearing on the circulation when rigid arteries were present massage and potassium iodide were of much benefit; if high tension, aperients like blue pill and magnesium sulphate with nitrites, and other substances lowering blood pressure. If cold feet caused sleeplessness, putting them in cold water, followed by dry rubbing, gave relief; dryness of the skin as a cause was relieved by warm bath or sponging; if due to indigestion alkalies for the acidity or diluents in the form of hot water with light meal before going to bed were indicated. Sometimes an empty stomach was the cause of sleeplessness by indirectly causing plethora of the cerebral vessels; in such a case, moderately warm food was the best remedy. Cooling the patient by wet pack, a cold sponging or affusion when the heart's action was accelerated by pyrexia, was often of great value. The action of drugs on the nerve cells, such as tea, coffee, etc., was discussed in relation to the production of sleeplessness. Such substances belonged to the group of derivatives of nitrogenous waste; lactic acid was probably the substance derived from normal muscular waste which acted as a hypnotic. Urea had no hypnotic action because it could not attach itself to the nerve cell. Alcohol could probably not only attach itself to the nerve cell, but had probably also the power of linking on other substances. The action of urethanes—an alcohol in combination with urea—was referred to. Chloral was mentioned as the first pure hypnotic to be used, and its depressing action on the heart was referred to; but in gouty people, with high tension, this was in itself an advantage. The use of sulphonal, tetronal, and trional, of which the second was probably less useful than the other two, as hypnotics, and of valerian as a sedative, was alluded to. The value of opium, both as a direct hypnotic and as an analgesic, was emphasized; the advantage of its subcutaneous and rectal injection was pointed out. In regard to pain, there was considerable difference of sensibility in different persons, also in the same person at different times. The influence of alkalies in relieving pain was probably usually by raising the alkalinity of the blood. For the pain of gallstones a small dose of chloroform to produce unconsciousness, combined with the injection of opium to maintain it, was good. In angina pectoris, opium was sometimes indicated, but nitrites were more generally useful. For periodic headaches, sodium salicylate in combination with bromide given the night before the headache was expected, was advantageous.

Prof. CUSHING limited his remarks to the hypnotics. He combated the idea that hypnotics should be avoided because they tended to reduce the bodily resistance to disease; when given in moderate doses this was slight, and sleeplessness itself had this depressing influence. By giving hypnotics not only might sleep be induced, but a vicious circle might be broken. The idea hypnotic was still to be found; it should act solely on the central nervous system and chiefly on the brain; it should not act on other organs; it should have a large margin between its hypnotic and tonic effect, and it should not produce tolerance, requiring the dose to be increased to produce similar effect. Their ill effect in producing early excitement, their uncertainty in action, their prolonged action, especially, were some of the difficulties alluded to in exhibiting the usual hypnotics. More than twenty years elapsed between the first anesthetic and the first hypnotic. Hypnotics might be divided into two groups—those which contained chlorine in their molecule and those which did not. Chloral not only depressed the heart but acted deleteriously on the tissues of the body generally, but this depressing action on the heart had been overestimated in importance and degree. All the chlorine hypnotics had a similar depressing action. Chloral still stood as the best of the chlorine-containing hypnotics. Alcohol, he considered, was one of the less dangerous hypnotics; its action in this relation was due to its depressing action on the brain; paraldehyde and amylene hydrate had a similar effect. Of the sulphur compounds, sulphonal was uncertain in its action and caused tissue changes, as indicated by the occurrence of hematoporphyrin in the urine; sulphonal and trional he believed the most dangerous of the hypnotics at present in use. The urea compound, urethane, was an excellent hypnotic when it acted, but it had to be used in very large quantities, as it was weak. Veronal had the advantage of acting with comparative certainty in small doses, and without deleterious effects, as a rule—acting, moreover, only on the brain. It seemed to

be the best of the non-chlorine hypnotics, and, along with chloral, one of the best of all the hypnotics. Of the older vegetable hypnotics, morphin hypodermically was of great convenience; it had seemed to him that the slight pain of the injection had had an attraction for neurotic patients. Hyoscyamus and hyoscine were of use, but hyoscyamine had no hypnotic action. They were, however, very uncertain in their action, and tended to produce delirium and other untoward effects, dilatation of the pupil, dryness of the throat, etc. The racemic form of hyoscine was much less liable to act on the peripheral organs, and had an equal hypnotic effect. Cannabis indica failed to act in many cases, and often produced excitement before it produced sleep; many of its bad effects were due to the impurity of the preparation. Its active principle might prove of more value, particularly in combination with bromide. When acute pain was present opium had to be employed, but the antipyrin group might be substituted, especially when the pain arose from the nervous system itself, but not from acute inflammation.

Sir William Broadbent held that before recourse was had to hypnotics an effort should be made to identify and remove the cause of the sleeplessness. Reference was made to indigestion as a frequent cause of sleeplessness which came on in the middle of the night. If the sleeplessness were from anxiety, when the patient got to sleep he usually remained asleep. In the former case the cause was largely mechanical, and anything such as a drink of water, by displacing a few cubic inches of gas, might be effective. Coldness of the feet was not, he considered, in itself the cause of sleeplessness, being merely a part of a general arterial contraction; for such the local use of cold water was the best. It was most important to be on the look out for digestive disturbances. High arterial tension was another prevalent cause of insomnia, and a calomel pill was the best hypnotic in such a case, acting long before it influenced the bowels. Extreme low tension was also a cause, sleep in the horizontal position being impossible; yet such a person might fall asleep in his chair after a sleepless night. There was no ideal and certain hypnotic. The effect of all depended as much on the condition of the patient as on the activity of the drug. In employing hypnotics the greatest care should be taken to guard against their habitual use. The injurious influence of chloral on the heart was very evident in such pulmonary conditions as emphysema and bronchitis.

Dr. Hale White believed that the first point to make out in investigating a case of sleeplessness was whether it was real; sometimes insomnia was imagined, and sometimes it was dreamed. The phenomena of sleep might be causal or associational. People who had sleeplessness from worry, the commonest cause, should not, he thought, be called in the morning. The second commonest form was that associated with indigestion; a little water or food given to such patients who woke in the early morning might send them off to sleep again. Such insomnia was especially prevalent when the indigestion was associated with diarrhea, a flatulence, but not with constipation. Excessive exhaustion was often a cause of sleeplessness, and it might be a sequel of acute fevers. As caused by disease, there were two groups in which hypnotics should be given—one in which the disease was incurable and speedily fatal, as in cancer, and in the other, in which the disease was limited, as pneumonia. He argued for the use of Dover's powder in pneumonia, and opium in heart disease, in certain cases. In both these groups of cases it was cruel to withhold morphia, but if the disease were incurable and long lasting, as in neuralgia and tabes, it was cruel to give it. Warmth, fresh air, quietness, position, darkness as factors in inducing sleep were mentioned. The value of alcohol as a hypnotic was, he considered, much exaggerated, so much had to be taken to get its depressing effect; a little warm food, such as warm milk was, he considered, preferable. Drugs for sleeplessness should never be given in the form of compressed tablets, for absorption was so slow and incomplete. Chloral had the advantage of being soluble, and had no markedly ill effects when given in small doses; but it was bad in the presence of nausea and sickness. Chloral amid he believed to be of great use in cases of heart disease; given in brandy and water, it was very soluble. Trional he had thought the best of the three sulphur hypnotics. They should not, however, be given in kidney disease, in view of the tendency to hematoporphyrinuria. Paraldehyde was a good hypnotic; it did not depress the heart, and was soluble; its disagreeable taste was probably an advantage. It was especially valuable in insomnia in cases of delirium or in abnormal mental states. Hyoscine should probably be rarely given; it, too, was especially indicated in the presence of mental aberration.

Dr. W. Collier asked why more sleep was wanted in winter than summer. Sleeplessness did not occur unless there was an irritable condition of the brain cells. School pressure he believed to be a fertile cause of insomnia, especially that involved in the competition for preparatory school scholarships. He had only in one case seen harm from chloral in the way of establishing a drug habit, but often from opium. Hypnotics in general he believed to be better than alcohol.

Dr. A. Foxwell emphasized the importance of circulatory insomnia. The vasomotor system in the brain did not appear to have any active function, thus an increase of general blood pressure meant an increase of sleeplessness. It was temporary elevation of blood pressure that had the worst effect in producing insomnia. Calomel might act in virtue of its stimulating action on excretory cells, and might with advantage be combined with rhubarb. In cases of sleeplessness from low blood pressure a full dose of strychnine was of value. In both cases the use of hypnotics might be combined, and a smaller dose would be effective.

Dr. Bertrand Dawson, in discussing the treatment of pain, said the great need was a peripheral anodyne to be applied locally; the mere assuagement of pain, in fact, facilitated the processes of healing. Central anodynes for local ulceration were not desirable. Of such, cocaine, eucaine and edrenalin were effective, but too transitory in their effect. Orthoform and anesthesia were of more value. Both were, however, insoluble, but they could be used as insufflations or ointments. The relief of pain, as in ulcerative stomatitis, he had found, might last ten hours. Given internally, they might relieve the pain of gastric ulcer or cancer. The combination of anodynes and hypnotics was advocated.

The President, Dr. F. M. Pope, thought that paraldehyde was especially valuable for chronic drunkards.

**Diagnosis of Pleural Effusions.**—Dr. W. Hadley then read a paper on the diagnosis of the varieties of pleural effusion, with especial reference to the recognition of tuberculous effusion. Cultural and inoculation methods gave 40 per cent. of positive results; the tuberculin method 70 per cent. of positive results. He also dismissed the method of artificially digesting the clot of the effusion, centrifugalizing the result and making cover-glass preparations for the bacilli, the method of cytodiagnosis, and that of serum-diagnosis on the agglutination principle.

**Influence of Posture on Breath Sounds.**—Dr. W. B. Ransom read a paper on the influence of posture on breath sounds, particularly in bronchitis and emphysema, but also in capillary bronchitis and in localized pulmonary tuberculosis—adventitious sounds being absent in the erect posture and becoming audible when recumbent. Possible explanations were advanced.

*Second Day—Thursday, July 27.*

**Discussion on the Pathology, Diagnosis, and Treatment of Various Forms of Meningitis.**—Dr. Howard Tooth opened a discussion on this subject, basing his remarks on 45 cases of meningitis of various forms that had been under observation at St. Bartholomew's Hospital. Of these 22 were tuberculous, 11 post-basic, 2 pneumococcic, 3 streptococcic, and 3 purulent, but of undetermined nature. Cer-

tain factors which were considered of importance in differential diagnosis were considered, including the earliest symptoms of onset, the duration of the cases, mental symptoms, optic neuritis (which was common in the tuberculous form, but less so in the others), amaurosis without fundus changes being met with in only one of the cases; retraction of the upper eyelids, which was taken as evidence of muscular rigidity, and squint, which was mostly internal and was very common but often transitory, and occurred almost invariably in the posteria basic cases. Tonic muscular spasm occurred in 74 per cent. of the cases, and included head retraction, opisthotonos, Kernig's sign, etc. This sign was almost invariable in the posterior basic form, but less so in the others. The cause of the spasm was considered to be cerebellar irritation. The reflexes were very variable in the cases, but in twelve the knee jerks were absent. General broad features in relation to the temperature curve were pointed out; in fatal cases the pulse and respiration rate fell whether the temperature fell or not. In the meningococcic form the curve was characteristically oscillating—a pseudohectic type differing from that of phthisis, however, in there not being any special time for the rise. In the epidemic form of meningococcus meningitis the course was shorter; in the pneumococcus form it was shortest of all, and most invariably fatal. In the tuberculous form the duration was, on an average, about 14 days, and it was almost invariably fatal. In the pneumococcus form the duration varied from 21 to about 100 days. In convexity cases the duration was shorter. In the epidemic form the duration was about 11 days. As to prognosis, in the meningococcic cases there were only 8 deaths in 17 cases, suggesting that an antitoxic treatment might be found to be useful. The most speedily fatal cases were the pneumococcic. Of 65 patients, seven recovered and one was recovering; four of these were meningococcus infections, and two were in perfect health one year later; of two others, one was blind and had mental deficiency, and a second was mentally deficient and had ataxy. As to treatment, there were no drugs that had any specification. When a meningoencephalitis was fully established, no conceivable operation could be of any avail. Removal of fluid by lumbar puncture in milder cases might aid a strong tendency to recovery, but that was all. It was in the direction of an antitoxin treatment, especially for the meningococcus cases, that the greatest hopefulness lay.

Dr. T. J. Horder described the pathological features of the cases described, based chiefly on an examination of the cerebrospinal fluid obtained by lumbar puncture, the method being given in detail: In 65 cases, 30 lumbar punctures were made; these included 10 meningococcus cases, 1 streptococcus, 15 sterile cases, and 2 contaminated. Of the 15 sterile 12 were shown to be tubercular. In 2 cases rapid improvement followed lumbar puncture. Meningococcus cases showed high leucocytosis, the pneumococcus lower, and the streptococcus cases lower still, due probably to the virulence of infection. Tuberculous cases showed a definite leucocytosis. The meningococcus cases could not be regarded as cases of a general blood infection. Pneumococci and streptococci were obtained from the blood. The probable avenue of infection seemed to be in some cases from the nasal mucous membrane. The commonest organism was the bacillus tuberculosis, occurring in 50 per cent. of the cases; the focus of dissemination being most often in children a tuberculous gland, in adults some longer bone lesion. In 15 per cent. of cases the meningococcus was the causal organism. Its morphological and cultural characters were described, and its relations to the micrococcus cattarhalis were hinted at. The probability of an active serum being obtained by injection of cultures into the horse did not seem from recent experience to be great. The streptococcus causing meningitis was sometimes streptococcus pyogenes and sometimes other forms. A mixed infection seemed to indicate old ear disease as the source. Pneumococcus cases suppurated with great rapidity, and streptococcus cases fairly constantly; it was unlikely that the streptococcus cases that had recovered had ever gone on to suppuration. All cases of acute meningitis tended to become cerebrospinal.

Professor Osler discussed the recent outbreaks of cerebrospinal fever in America and elsewhere. Cases of posterior basic meningitis were doubtless sporadic cases of this disease. In epidemic peculiarities it most closely resembled pneumonia, the similarities and differences between the two being pointed out. Infection of the meninges probably took place from the nasal and nasopharyngeal regions. There was evidence to indicate the contagiousness of the disease. The infectivity was probably similar to that of pneumonia. Of ninety-three cases of meningitis, thirty-five were tuberculous, and thirty-two cerebrospinal fever.

The diagnosis was rarely in doubt—evidence of meningitis with purpura, etc., the spinal overshadowing the cerebral symptoms, the meningococcus being found in the cerebrospinal fluid and recovery occurring, being strong warrant that the disease was due to the diplococcus intracellularis. The ultimate prognosis in these cases was more favorable than in the others. Where pressure was high repeated lumbar puncture had been followed by good results. In a few cases there was a meningococcus septicæmia. The cases that recovered completely might not have had so much exudate.

Dr. Montague Murray referred to the constancy of the rigidity in meningococcus cases of meningitis, but it had seemed to him to be variable in individual cases. He referred to a probable case in which consciousness was abolished for nine months and recovery occurred with only slight mental enfeeblement.

The President, Dr. F. M. Pope, referred to two cases of pneumococcal meningitis and to one case of pachymeningitis hæmorrhagica.

Dr. C. N. B. Camac referred to the nasal mucous secretions in relation to meningitis.

Dr. S. West alluded to the occurrence of periodic respiration in meningitis. When the Cheyne-Stokes type occurred death in his experience always occurred, while in the cases with merely grouped respiration recovery was not uncommon.

Dr. St. Clair Thomson also referred to the nasal mucous membrane as a source of infection, alluding to four of his own cases of meningitis associated with nasal disease.

Dr. W. B. Warrington discussed the question of the value of lumbar puncture in the differential diagnosis of meningitis, from the so-called pseudo type.

Dr. T. F. S. Caverhill described an instance of recurring epidemic meningitis in an institution, in which sudden death occurred in several instances.

Dr. Tooth in reply alluded to the after history of the cases and maintained that several years had to pass before an opinion could be given as to the completeness of recovery. Some cases of epilepsy, for example, might have been sequels of meningitis.

**Human and Bovine Tuberculosis.**—Dr. Nathan Raw then read a paper on human and bovine tuberculosis with special reference to bovine infection in children, arguing that the two were distinct, so that either might occur in the human subject and that there was evidence to show that the two might be mutually antagonistic. The paper was discussed by Dr. R. Pratt, Dr. F. H. Jacob, Sir W. Broadbent, and Dr. S. West.

Dr. F. J. Poynton read a paper on the employment of citrate of sodium in infant feeding, used to make the clot less dense, in the strength of one grain to the ounce.

*Third Day, Friday, July 28.*

**Discussion on the Diagnosis and Treatment of Cardiac Degeneration Apart from Valvular Disease.**—Dr. J. Dreschfeld opened this discussion, first dealing with acute myocarditis, particularly that associated with typhoid fever, diphtheria, pneumonia and influenza. The clinical signs were enumerated and the course of each described. In such cases digitalis was not indicated, but ether, camphor,

strychnine, etc., and alcohol should be given with caution. besides this, methods of depletion by leeching, venesection, etc., were often useful. Chronic myocarditis developing from the acute form or more insidiously, was then described with its signs and course. Myocardial affections in connection with chronic infectious diseases were next taken, as in syphilis, malaria and tuberculosis, the syphilitic form being especially discussed. Persons who had had or might have had syphilis should certainly be subjected to antisyphilitic treatment. The next group of cases to be discussed were those of cardiac insufficiency due to chronic intoxications which might be exogenous, as alcohol tobacco and lead, or endogenous, as in Bright's disease, diabetes, gout, Graves's disease, cancer and cachexia in general. The alcoholic and tobacco hearts were especially considered. The treatment of the alcoholic form was mainly rest and attention to diet, but in some cases considerable quantities of alcohol seemed to be indicated.

Heart degeneration due to arteriosclerosis was next referred to. It was sometimes associated with a true angina and sometimes with a false angina. In its treatment especial attention was needed to diet, with little alcohol, rest, if hypertrophy and high tension were present potassium iodides and nitrites should be given; if low, strychnine. Any distressing symptoms were to be relieved. Heart muscle failure in chronic lung affections, especially emphysema and chronic bronchitis, was the next group. Where there was no great œdema or ascites digitaline was of value; if these were present then aperients were first to be given and venesection practised if there were much dilatation of the right side; food should be given in small quantities and alcohol only in measured quantities. For the heart strain due to excessive muscular exercise the treatment was that of general cardiac insufficiency. For fatty heart, the symptoms of which were ennumerated, in mild cases the body weight should be cautiously reduced, potassium iodide given if there were high tension, and if signs of dilatation were present first digitalis should be given and then effort should be made to reduce the weight of the patient. The senile heart was lastly discussed.

Dr. W. P. Herringham considered that the largest class of cases of heart muscle failure were in elderly people and among them those in whom the heart hypertrophied lived a few years longer than those in which it did not. In the former the heart reacted to the stimulus of increased peripheral resistance, in the latter it did not. This increased resistance was principally due to endarteritis depending it might be on blood impurities due to errors in diet of middle life, especially in the matter of excess, or to acute fevers, as typhoid, rheumatism, or syphilis. Reference was made to cases of heart failure in adolescents and to those in which the cause was overstrain.

Dr. A. Foxwell limited his remarks to the chronic types of cardiac degeneration. Syphilitic disease of the myocardium rarely occurred alone, there was nearly always some degenerative disease of the valves, dilatation of the aorta and degeneration of the larger branches of the pulmonary artery. The occurrence of pulmonary atheroma in chronic indurative lung diseases was referred to. The influence of such in producing hypertrophy of the right heart depended largely on the amount of exertion required to be made by the patient. Allusion was made to the tendency to heart failure occurring in families. The importance of such patients living down to their strength was insisted on. A fatty heart was hardly ever a large heart. The treatment of the chronic conditions of myocardiac disease was a question of the careful balancing of one part of the organism against the other. The heart was never alone affected.

Dr. J. Hay confined his remarks to the condition of the venous pulse in the neck in cases of cardiac degeneration, maintaining that in them the auricular contraction was not before but simultaneous with the ventricular contraction.

Dr. S. West referred to the cardiac dilatation that occurred in pyrexia, with a toxic factor superadded in the case of such infective fevers as typhoid, rheumatic fever and influenza.

In the course of infective diseases heart failure might be quite sudden in onset and speedily fatal. The effect of even moderate strain in causing dilatation was very obvious in chlorosis, in valvular disease, and in pericarditis. Allusion was made to the effect of failure of the heart on the heart itself, the first veins to feel the influence of back pressure were the coronary veins, and venous congestion of the heart muscle favored cardiac dilatation. Allusion was made to the extraordinary susceptibility of degenerate heart muscle to the action of digitalis from accumulation.

Sir James Grant emphasized the fact that patients might live a comparatively vigorous life for many years with serious cardiac changes and insisted on the importance of maintaining a healthy action of the skin in myocardial diseases.

Dr. N. Ewart referred to the importance of regulated exertion in maintaining cardiac health, the importance of time being given for heart treatment, and the use of the adrenalin group of substances in heart affections.

The President, Dr. F. M. Pope, had never seen instances of acute heart strain during the winter, suggesting that blood temperature might have influence in its causation.

**Diagnosis of Ulcer of the Stomach.**—Dr. Bertrand Dawson then read a paper on the diagnosis of gastric ulcer, largely by microscopic chemical method, in the course of which he argued that an attack of hæmatemesis should not be treated surgically by an emergency operation.

Dr. Mackenzie Davidson read a paper on the diagnostic value of the *x*-rays.

(To be continued.)

## AMERICAN SURGICAL ASSOCIATION.

*Twenty-sixth Annual Meeting, Held at San Francisco, July 5, 6, and 7, 1905.*

President, Dr. Geo. Ben Johnson, of Richmond, Va.

(*Concluded from page 240.*)

**Tuberculous Conditions of the Spine Requiring Surgical and Mechanical Relief.**—Dr. De Forrest Willard of Philadelphia stated that the principal surgical measures employed for the relief of spinal caries were laminectomy for paraplegia; forcible immediate straightening of the kyphosis; forcible gradual straightening; erasion of carious bone; wiring of spinal processes; evacuation of pus accumulations; long-continued fixation of the column, and hygienic measures to prevent the necessity for operative interference. Complete, methodical, and long-continued fixation of the spine in the position of hyperextension, with healthful surroundings in the sunlight, were the prime factors in securing new ossific deposit necessary to replace the carious bone. Laminectomy for paraplegia was advisable only after long-continued and patient treatment along the above-named lines from one to two years, since the prognosis, especially in children, under these conditions was favorable and good powers of locomotion might be confidently expected. The operation was justifiable in selected cases where loss of motion and sensation were progressively worse and the symptoms threatened life. If the tubular masses within the spine could be removed, and if extradural pachymeningitic deposits or pus could be taken away, improvement might be expected, and in many cases relief occurred. The operation had a mortality of about 25 per cent. from immediate shock, 36 per cent. within a month, while one-half the cases died within the next year, their lives being probably shortened by the operative procedures. Cases of non-improvement and death equaled nearly 65 per cent. Forcible immediate straightening of the kyphosis was an unsurgical and dangerous proceeding; it was liable to reawaken the tubercular disease and to weaken the column. Forcible gradual straightening by supporting the kyphotic area upon a pedestal was a valuable agent in relieving deformity. The weight of the shoulders and pelvis could thus be utilized as straightening forces.

and the weight of the column thrown upon the posterior arches. In this position it was permanently fixed by plaster of paris. Complete erasion of the carious bodies of the vertebræ was an uncertain operation, in the dorsal region requiring section of ribs, with danger of wounding the pleura. Wiring of the spinous processes had never been sufficiently tried to demonstrate its helpfulness. Spinal abscesses which contained only liquefaction of caseation should be aspirated. When true pus formed, asepsis through drainage was advisable.

**Tumors of the Spinal Cord.**—Dr. J. Collins Warren of Boston read a paper on this subject, in which he reported three cases of tumor of the spinal cord operated on with good results.

**Spina Bifida.**—Dr. James E. Moore of Minneapolis, Minn., read a paper on this subject, in which he presented an analysis of 385 cases treated by excision. A careful study of these reported cases illustrating the experience of many surgeons, justified him in drawing the following conclusions: "(1) Operation upon children of very tender age is scarcely worth while, because it is accompanied by so large a mortality rate, and because it does not stop the progress of progressing cases. (2) Patients five or more years old can be operated upon safely. (3) Patients with large or rapidly growing tumors, with hydrocephalus and with paralysis or deformities of the extremities are not cured. Finally, all we can hope to accomplish by operation for spina bifida is to relieve the patient of an unsightly and annoying tumor after he has survived the dangers of the affliction *per se*."

**Exophthalmic Goiter Treated Surgically.**—Dr. Thomas W. Huntington of San Francisco, Cal., said that during the past three years he had treated surgically nine patients suffering from exophthalmic goiter. In each instance partial ablation of one or both lobes of the thyroid was done, and one patient was subjected to three operations successively. Seven were females, and two were males. The ages ranged from 28 to 56, the average age being 42 years. In five patients the development of symptoms of Graves' disease was associated with preexisting enlargement of the thyroid. Two of these were cystical colloid. In four the development of characteristic symptoms were simultaneous with glandular hypertrophy. All of these were colloid. In the five cases where the exophthalmic condition developed secondarily, preexisting glandular hypertrophy was noted during a period of six, ten, thirty-four, thirty-five, and thirteen years respectively. In this series exophthalmic symptoms had been noted one, two, three, two, and two years prior to operation, the average being one and four-fifths years. Duration of symptoms in the primary or pure Basedow cases prior to operation was two years, three months, two months and one year, the average being seven and one-fourth months. In this series eight patients survived the operation and were now living. One patient died on the twelfth day. The eight living patients were carefully watched, and their status definitely recorded up to date. The author gave a detailed account of each case as it occurred. A wider experience in this particular field had increased his faith in the value of surgical interference in carefully selected cases, and in conclusion he repeated what he wrote in an earlier communication, namely, the argument for early operation in malignant disease applied here with equal force. Extirpation should be undertaken before destructive changes had occurred, before the function of important organs was seriously, perhaps permanently injured, and the patient's vitality lowered by chronic thyroid intoxication.

**A Review of Five Hundred Cases of Gastroenterostomy, Including Pyloroplasty, Gastroduodenostomy, and Gastrojejunostomy.**—Dr William J. Mayo of Rochester, Minn., stated that this included all the cases operated on by Dr. Charles H. Mayo and the writer during fourteen years in which an incision was made in both intestine and stomach, and plastic union established to increase gastric drainage. The death rate gave every case dying in the hospital without regard to the cause of death or the length of time after operation. Of pyloroplasty there were twenty-one cases with no deaths, and seven reoperations. Pyloroplasty had only a small field of usefulness. Finney's gastroduodenostomy, 58 cases, 4 deaths, 2 from other causes at a late date; only 1 death in the first 46. The author said that there was a large field of usefulness for this operation in narrow stricture following healing of ulcers, but it was less useful in unhealed ulcer. Of gastrojejunostomy there were 421 cases; benign, 307; death rate, 6 per cent. Last 140 cases, 4 deaths. Malignant, 114; death rate, 18 per cent. In the last 40, including radical operations for cure of cancer, 5 per cent. Murphy button, 157 operations—139 anterior, and 18 posterior. This was the operation of choice after pylorectomy and partial gastrectomy. McGraw ligature, 36 operations. This was the operation of choice by the anterior method in gastrojejunostomy for inoperable cancerous pyloric obstruction. Two hundred and twenty-eight posterior suture operations. Robson's bone bobbin, 16 operations, with 1 death. Mikulicz operation, transverse incision, 43 operations, with four deaths and four secondary operations. Moynihan operation on 9-inch loop, 53 operations, with 3 deaths; 7 reoperated for chronic bile regurgitation within 15 months. Roux-Doyen operation, 48 cases, 2 deaths, 2 secondary operations. Operation of choice was the Moynihan-Peterson without a loop, made by suture within 3 inches of the origin of the jejunum and obliquely on the posterior wall of the stomach with the inferior margin at the greater curvature near the junction of the pyloric end with the body of the stomach. In the last 80 gastrojejunostomies for benign disease there had been only 1 death.

**A Simple Aseptic Surgical Technique.**—Dr. Dudley P. Allen of Cleveland, Ohio, related observations which were based upon a series of 377 bacteriological examinations of the hands, made at the close of operation, and upon the clinical results obtained in 3,500 cases. The bacteriological investigations were conducted in five series. In series "A" the cleansing of the hands was with soap and water, scrub brush and nail cleaner. The hands were then sterilized in Harrington's solution. In operating the hands were encased in rubber gloves in which was sterile water. Twenty-six observations were made by taking cultures from the hands at the close of operation. In each case the cultures were negative. In series "B" the washing of the hands was as in series "A." Twenty-four observations showed that cultures were negative in each case. In series "C" the washing was as in series A," with the addition of thorough subsequent washing in 70 per cent. alcohol. In forty-two observations the staphylococcus pyogenes albus was found in eight cases, or in about 20 per cent. The conclusion reached was that alcohol was not efficient as a disinfectant, and did not prevent the development of bacteria within the rubber gloves containing no germicide but simply sterile water. From these observations it would seem probable that if bacteria developed upon the hands sterilized by alcohol, when in gloves containing simply sterile water, they would develop in the same manner upon the hands prepared in the same way if encased in dry gloves with powder, as the hands became moist with perspiration. In series "D" the hands were prepared as in series "C," and then washed in a solution of bichloride of mercury, 1-5,000, and encased in rubber gloves containing the same solution. Sixty-four observations were made. All were negative except one. In this were found the staphylococcus pyogenes albus. In series "E" the hands were washed as in series "A," and then thoroughly washed with a solution of bichloride of mercury, 1-5,000, and encased in rubber gloves containing the same solution. One hundred and two observations were made. The Hay bacillus was found in one case. In series "F" the hands were washed as in series "D," and then cleansed in a solution of bichloride of mercury, 1-3,000, and encased in gloves containing the same solution. Seventy-five observations were made. The staphylococcus pyogenes albus was found in a single case.

The clinical observations were made upon a series of 967 laparotomies. Of these 687 were clean and 288 were septic before operation. There were 2,533 operations other than laparotomies. This gave a total of 2,139 clean operations. For the purpose of study the clean cases only were taken, since the question of asepsis evidently could not be studied in cases septic before operation. Tables were presented by the author showing the results obtained in all of the various series of operations, as in hernia, varicocele, varicose veins, and laparotomies of all kinds, and other miscellaneous operations. The results showed from the whole series of 2,139 clean operations but two deaths from sepsis. Erysipelas developed but once. Stitch abscess occurred in fifty-eight cases, or in about 2.25 per cent. The method of cleansing the hands finally adopted was to wash them thoroughly with soap and water, using the scrub brush for the palms of the hands, but only slightly upon the backs of the hands, and never upon the arms, the object being to avoid irritation of the integument. The nail cleaner was used only beneath the nails, and not around the bases of the nails. The hands and arms were then washed in a solution of bichloride of mercury, 1-5,000, and encased in rubber gloves containing the same solution. The belief of the writer was that the continued action of the solution of bichloride of mercury in the gloves was a fundamental safeguard in preventing the developement of bacteria within the gloves during operation. That this was true in practice was shown by the results obtained in the large number of cultures taken at the close of operation. The conclusions reached from the various series of cultures and clinical cases were, first, that Harrington's solution, although efficient, was undesirable, since it caused marked irritation of the hands and arms. Second, that washing of the hands and arms should not be too violent, and that the use of the scrub brush should be confined to the hands. The arms should be washed by rubbing with gauze or a towel. The use of the nail cleaner about the base of the nails was unnecessary. Alcohol was not adequate as a germicide when used upon the hands. That a solution of 1-5,000 bichloride of mercury, used after washing to disinfect the hands and arms, and then used in the rubber gloves, was thoroughly satisfactory in protecting against the development of bacteria within the gloves during operation. That the rubber glove was a guarantee of safety, not only to the patient, but to the operator himself, when operating upon infected wounds. That a mask over the face was not necessary.

**Intussusception.**—Dr. Maurice H. Richardson of Boston, Mass., reported a case of intussusception in a boy of four. Vomiting and pain, with intestinal obstruction and a tumor in the left abdomen, suggested very strongly the diagnosis. The operation showed an invagination of the small into the large intestine, so firm that reduction seemed impossible. The child's condition was so bad that an enterostomy was performed, in the hope that a cure would be effected by spontaneous sloughing of the invaginated gut, life meanwhile being maintained through the enterostomy. Unfortunately, the child died at the end of eighteen days, the immediate cause of death being a purulent bronchitis. At the autopsy no trace of the intussusception could be found. A careful search through the literature showed no case of spontaneous reduction of an intussusception in which the chain of evidence was absolutely complete. In this ease the diagnosis made before operation, and demonstrated before the staff of the Massachusetts General Hospital and a large audience, was unassailable. The lesson taught by this case would seem to be that greater efforts should be made for reduction, either by hydraulic or air pressure through the rectum, or by manipulations after the abdomen had been opened. In the reader's experience, however, the results have been fatally compromised by just such efforts. It seemed, therefore, questionable whether, in view of the great rarity of spontaneous reduction and of the almost universal failure of the milder palliative measures, one will ever be justified in selecting any but those operative measures which, undertaken at the earliest possible moment, cannot fail to remedy completely and effectively the disease.

**Constriction of the Duodenum Below the Entrance of the Common Duct and Its Relation to Disease.**—Dr. A. J. Ochsner of Chicago read a paper with this title. In a series of cases operated upon for the relief of cholecystitis it was found that there was frequently present a constricted condition of the duodenum just below the entrance of the common duct. This was usually accomplished with dilatation of the duodenum above this point. The dissection of a number of cadavers demonstrated the fact that there was present a marked increase in the circular muscular fibers of the duodenum, beginning at a point from 1 to 3 cm. below the entrance of the common duct, and extending for a distance of 1 to 4 cm., forming a broad sphincter. It seemed likely that this sphincter had much to do with the physiological function of the duodenum, facilitating the mixing of chyme with bile. It also seemed likely that this sphincter served the purpose of establishing a condition of rest in this portion of the alimentary canal in case of irritation of the biliary or pancreatic ducts. The paper was fully illustrated, and the author gave a tabulated list of fourteen cases of dilatation of the duodenum which he had met with among his patients operated for the relief of gall-bladder disease.

**Perforation of the Gall-Bladder.**—Dr. Archibald Mac Laren of St. Paul, Minn., read a paper on this subject, in which he reported ten cases, and said that gall-bladder perforations were comparatively rare, especially if observations were confined to ruptures due to violence, ulceration, and gangrenous inflammations. But if we added to these the cases of cholecystitis in which inflammatory products had evidently escaped from or passed through the wall of an inflamed gall-bladder, even though we may not find the perforation itself, the number of cases was considerably increased. Such abscesses about the gall-bladder, either in the free peritoneal cavity or in the neighboring liver tissues, were rare as compared with appendiceal abscesses, but were not uncommon, and unquestionably should be included when studying perforations of the gall-bladder. Fistulous passages between the gall-bladder and duodenum, stomach, or colon were, of course, due to perforation of the gall-bladder. Most perforations of the gall-bladder occurred in neglected cases where gallstones had been known to exist for long periods of time, and where the patient had had ample warning through many attacks of biliary colic. Of Robson's 539 operations on the gall bladder and bile-ducts, twenty-five of these cases could be fairly said to be perforative in character. Dr. Mayo, in 328 cases, found sixteen perforative cases. Dr. Ochsner, in forty-eight cases operated upon, found one perforation. He had operated upon eighty gallstones cases, nine of which were perforative in character and one post-mortem, making a total of ten, which seemed a large proportion as compared with other lists of cases already on record. There were eight recoveries and one death. In this fatal case he believed that the result would have been the same even though the gall-bladder had been removed, because gangrene of the gall-bladder and neighboring liver tissue, and especially in the presence of a localized abscess, any operative work which disturbed the abscess wall would only have spread the infection and lessened the chance of recovery. He believed that in any perforative case which had gone on to the formation of a localized abscess, the wisest course was to open and drain the abscess, waiting until a later time to deal with the gallstones or the disease of the gall-bladder.

Dr. Emmet Rixford of San Francisco read a paper in which he discussed the subject of excision of portions of the chest wall for malignant tumors, and reported cases upon which he had operated.

**Officers.**—The following officers were elected for the ensuing year: *President*, Dr. Albert Vander Veer of Albany, N. Y.; *Vice-Presidents*, Dr. James E. Moore of Min-

neapolis and Dr. John C. Munro of Boston; *Secretary*, Dr. Dudley P. Allen of Cleveland, Ohio, reelected; *Treasurer*, Dr. Geo. R. Fowler of Brooklyn, N. Y., reelected; *Recorder*, Dr. Richard H. Harte of Philadelphia, Pa.

Cleveland, Ohio, was selected as the place for holding the next annual meeting, the time for which is to be fixed by the Committee on Annual Meeting.

## New Instruments.

### A LIGATURE-CARRYING NEEDLE.

By GEORGE FRANKLIN SHIELS, M.D., F.R.C.S.E.,

NEW YORK.

WHILE I do not claim any great originality for the ligature-carrying needle, which is herein described, still it has proven so useful to me in abdominal and pelvic work that I venture to make it known in the hope that it may be of practical benefit to others.

The instrument is simply a straight nickel-plated malleable steel needle with a blunt point and a large eye; in cross section it is oval in shape, *not round*. It is not too thick to be carried in any ordinary needle holder, and not sharp enough either in edge or point to injure tissues or vessels. The large eye is to permit of easy threading. Three of these needles will answer all purposes—one and one-half, two, and three inches long.

The points of advantage are:

1. While it is rigid enough to perforate omentum, broad ligaments, adhesions, muscle, mesentery, etc., still it can, by the surgeon's fingers, be immediately and easily bent to have any shape that he may wish—full curved, half curved, straight, angular, etc., etc.

2. It can be used with any ordinary needle holder.

3. It does away with the necessity for all other ligature carriers and aneurysm needles, since it can be passed either point or eye first.

4. It is inexpensive. The manufacturers tell me that they can produce it for fifty cents per needle—*i. e.* one dollar and fifty cents for the set.

39 WEST THIRTY-FIFTH STREET.

## Books Received.

*While the* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE CRUX OF PASTORAL MEDICINE. THE PERILS OF EMBRYONIC MAN: ABORTION, CRANIOTOMY, AND THE CESAREAN SECTION; MYOMA, AND THE PORRO SECTION. By REV. ANDREW KLARMANN. 12mo, 162 pages, muslin. Fr. Pustet & Co., New York.

MATERNITAS. A BOOK CONCERNING THE CARE OF THE PROSPECTIVE MOTHER AND HER CHILD. By CHARLES E. PADDOCK, M.D. 12mo, 189 pages, illustrated, muslin. Cloyd J. Head & Co., Chicago.

A PRACTICAL TREATISE ON FRACTURES AND DISLOCATIONS. By LEWIS A. STIMSON, B.A., M.D., LL.D. Fourth Edition. 8vo, 844 pages, illustrated, muslin. Lea Brothers & Co., New York and Philadelphia. Price, $5.00 net.

A TEXT-BOOK OF DISEASES OF THE CHEST, PERICARDIUM, HEART, AORTA, BRONCHI, LUNGS, MEDIASTINUM, AND PLEURA. By EGBERT GUERNSEY RANKIN, A.M., M.D. 8vo, 744 pages, illustrated, muslin. Boericke & Tafel, Philadelphia. Price, $5.50.

A MANUAL OF MIDWIFERY FOR STUDENTS AND PRACTITIONERS. By HENRY JELLETT, B.A., M.D., F.R.C.P.I., L.M. 8vo, 1158 pages, illustrated, muslin. William Wood & Company, New York. Price, $5.50 net.

PARALYSIS AND OTHER DISEASES OF THE NERVOUS SYSTEM IN CHILDHOOD AND EARLY LIFE. By JAMES TAYLOR, M.A., M.D., F.R.C.P. 8vo, 512 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $4.00 net.

## Medical Items.

**Contagious Diseases—Weekly Statement.**— Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 5, 1905:

| | Cases | Deaths |
|---|---|---|
| Measles | 223 | 8 |
| Diphtheria and Croup | 193 | 21 |
| Scarlet Fever | 47 | 1 |
| Smallpox | 3 | 1 |
| Chickenpox | 17 | ..... |
| Tuberculosis | 402 | 141 |
| Typhoid Fever | 122 | 13 |
| Cerebrospinal Meningitis | 24 | 12 |
| Typhus Fever | ..... | ..... |
| Yellow Fever | ..... | ..... |
| Cholera | ..... | ..... |
| Totals | 10,31 | 197 |

**Dog Sickness.**—Taussig says that this is the name under which a peculiar endemic gastric catarrh is known in Herzegovina. He observed 240 cases during the summer of 1904, and concludes that the malady is a distinct infectious disease, with the following characteristics: An incubation period of five to seven days, followed by a sudden rise of temperature, lasting two to three days, and ending by crisis. Other symptoms are severe headache, dizziness, and vomiting, slowing of the pulse, persisting constipation or diarrhea and anorexia, and muscular pains. The eyeball becomes red and tender, convalescence is prolonged, and there is great tendency to relapses. The disease, which occurs only during the summer months in certain regions of Herzegovina, appears to be transmitted by the bites of a certain species of gnat.—*Wiener klinische Wochenschrift.*

**Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ending August 5, 1905:**

### OPERATIONS FOR PROCIDENTIA UTERI.*

By W. M. POLK, M.D.,

NEW YORK.

One of the most trying defects which afflict women is procidentia uteri, and while much has been done to correct it, many women from the necessitites of their lives are doomed to carry the evil till life ends, even though it be long continued.

I am moved to call the attention of this Society to it, because it is sufficiently common to have come to the notice of all of you, and for the reason that its great cause, child bearing, and neglect in after life, are sufficiently common to come under the observation of every medical man, no matter in what direction his work may lie; it must, therefore, have something more than special interest. The numbers of devices for its cure, recommended by even high authorities, assures us that no one has yet hit upon the exact method to certainly remedy it, but this is all the more reason for agitation and suggestion. It is in this spirit that I present this paper.

I shall avoid allusion to any procedures save such as appeal to me as best meeting the difficulty, and proceed at once to the consideration of them. Roughly speaking, we may divide the lesion into partial and complete procidentia. The cervix closely followed by the uterine body reaching the ostium vaginæ in the first variety, while in the second these structures project more or less through this opening, and lie outside the pelvic cavity, carrying with them more or less of such adjacent organs as the bladder and rectum. Every operator agrees upon the fundamental importance of restoring, as far as surgical skill permits, the anatomical integrity of the outlet through which the protrusion occurs or is threatened, and to this end sets himself the task of bringing into normal relations, the levator ani, its subfascia, the perineal structures, and the lumen of the vagina. Could one disregard the functions of this canal, the task would perhaps be easier, but in the absence of such freedom of action it becomes one of the nicest and most complete in plastic surgery. Following the lines laid out by Emmet, however, a good operator can hope for great results in this field. In this paper, therefore, it is not necessary to say more concerning the pelvic floor and outlet than to emphasize the rule that all procedures looking to the correction of procidentia must be preceded or followed by an efficient repair of this floor and outlet as surgical skill will permit. This leaves us free to turn attention to two methods designed to supplement and perfect the work done upon the pelvic floor. The first considered is applicable to partial prolapse when retention of the uterus is desired, and has as its purpose the reduction of the size and weight of the uterus, and its removal from the posterior and lower parts of the pelvic cavity to the more advantageous one in the anterior and upper parts of this region. In the former position the organ is in the full current of all influences working towards procidentia, in the latter it is out of this current as far as circumstances permit. The second method is simply removal of the uterus and attachment of the vaginal stump to the anterior abdominal wall, and is applicable to complete prolapse. Attention is now asked as to the process by which these things may be done. As to the first—the cervix is amputated as high up as possible, that is as much beyond the vaginal junction as may be without entering the peritoneal cavity. This amputation is carefully conducted so as to avoid subsequent stenosis of the cervical canal, in other words, the lining of this canal is preserved well below the point of amputation, so as to give ample supply to be stitched to the lining membrane of the vagina, the cut edges of which are united lineally from side to side, the line of suture corresponding to about the base line of the broad ligaments, the cervical mucous membrane projecting and attached at about the center of this line.

Alexander's operation is the next step, and owing to the enlargement of the round ligaments always present in these cases, it may be relied upon to hold well forward the now lightened organ. Perineal repair closes the work.

Since suggested in 1883, this plan has been repeated a sufficient number of times to warrant a continuance of the confidence then expressed, a confidence fortified again and again by the inferior results obtained by the writer from the methods in more common use for partial procidentia. The second procedure was outlined as a remedy for complete procidentia at a meeting of the American Gynecological Society, in Philadelphia, in 1893 (see page 320-321, Volume 18, Transactions American Gynecological Society), when in a discussion of a paper by Edebohls upon the operative treatment of such cases, it was proposed to meet the condition by removing the uterus and stitching the stump of the vagina to the abdominal wall; it being stated that while certain cases might be treated by hysterorrhaphy as then proposed, it had been observed in certain cases of extreme prolapse with marked eversion of the vagina, that attaching the uterus to the anterior abdominal wall did not sufficiently take up the vaginal slack. It was proposed to meet such cases by removing the uterus and attaching the vaginal stump to the abdominal wall, experiments having been made to that end upon two patients with whom the process had been successful. This procedure, colporrhaphy, is a ready method of suspending not only the vagina but the bladder and rectum as well. I can add ten cases to the two already mentioned in all of whom good results are obtained, and so far as I know have been maintained. Two of these, however, have one year or less to their credit. In all of them a thorough operation for restoration of the pelvic floor preceded the colporrhaphy. In the later cases when there was unusual

*Read before the Practitioners' Society of New York, May 5, 1905.

elongation of the anterior vaginal wall with excessive prolapse of the bladder, Reynolds' operation for cystocele was combined with Emmet's operation upon the perineum and rectocele, but as this method

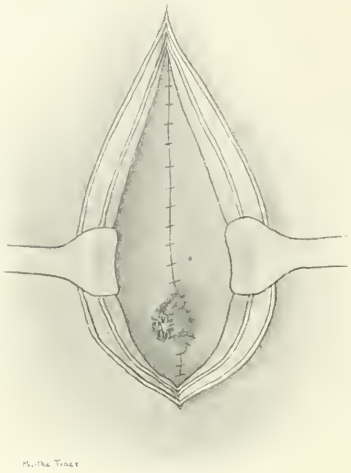

Fig. 1.

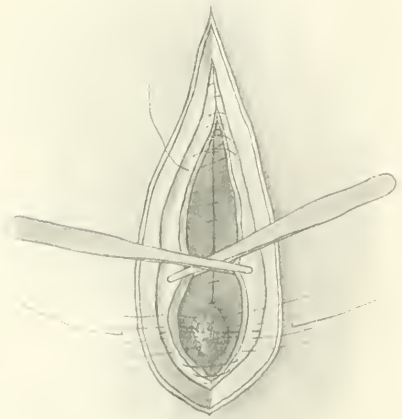
of treating cystocele shortens as well as narrows the vagina, one must be sure before using it that in so doing he does not so far shorten this canal as to deprive himself of vaginal tissue needed for fixation in



the abdominal wall, the fixation of the entire thickness of the vaginal wall in the abdominal wall being more efficient than mere fixation of its outer coat, that which is reflected upon the uterus, are the real

support of the base of the bladder in these cases. Therefore, every effort should be made to bring all the vaginal coats into the abdominal wall, and, if because of bulk, any part of this structure must be left out of the cut, it had better be the outer coat, this latter being brought no further than the peritoneum. If there be any doubt as to a sufficiency of vaginal tissue for this purpose, the operation for the cystocele must narrow but not shorten this canal, the Sims' or some similar operation being preferable.

*Colpo-orrhaphy.*—An opening about two inches long is made along side the linea alba, right or left as may be preferred, the lower end of the cut where it enters the abdominal cavity being about one and one-half inches from the inner face of the pubic symphysis. The condition of the uterus and appendages is next determined by direct palpation. When diseased these latter should first be removed, otherwise the ovaries should be left, but not the tubes. The uterus is next separated from the broad and round ligaments throughout, these structures being allowed to retract against the pelvic wall, ligation of them is

Fig. 3.

so conducted as to leave no raw surfaces exposed. In detaching the broad ligaments, care is taken to avoid injury to the uterine artery as it swings across the pelvic floor to the uterus, clamps alongside the uterus being used to check bleeding from that direction. This organ is now forcibly drawn upwards out of the abdominal cavity; it will be held back by the lines of fascia extending laterally beneath the broad ligaments, and by the uterosacral ligaments which approach each other at the surface of the uterus—the connections with the bladder are more yielding. If the chief resistance comes from the uterosacral ligaments, further traction should cease, and the line of attachment of the proposed stump be then and there determined, but if it comes from the line of fascia extending laterally, the uterus should be carefully separated therefrom by blunt dissection well down to the vagina. The main stems of the uterine vessels must be respected in this dissection, branches being freely ligated as one progresses. In women with the deep male pelvis, this separation will not infrequently be necessary, to get enough

of the vagina for our purpose, but as a good grip on the vagina is very advantageous, it should be done. If, in spite of this dissection we fail to approximate the vagina proper, we must be content with the cervix, or rather with its coverings. It is not necessary to directly disturb the peritoneal and fascial connections with the bladder for they come up readily; but why not free the stump from the uterosacral ligaments? because you wish to retain and even increase the support they give to the rectum and the bottom of Douglas' cul-de-sac. This is of the utmost importance in its relation to the subsequent and inevitable downward pressure upon the lower part of the posterior vaginal wall and the perineum. The uterosacral ligaments must, therefore, be preserved, and even their uterine ends included if necessary with the vagina in the abdominal incision. Your dissection will have left you a uterus free from all attachments, except to the vagina, the bladder, and the uterosacral ligaments. Drawing it upward to the lower angle of the wound, you fix the line at which traction is compatible with proper union and then amputate. Cut away flush with the outer abdominal surface and ligate the uterine vessels about midway between the skin and peritoneum, that is outside the peritoneal cavity. This insures the circulation in the stump till such time as good union is obtained. In making the amputation the connection of the uterosacral ligaments is to be avoided. As a rule, however, the line of amputation indicated, will carry us through the cervix above this connection. If there be cervical tissue in the stump this is trimmed out from within so as to lessen the size and give a wide opening into the vagina for drainage. Otherwise we proceed at once to fixation. All bleeding being checked, the stump is drawn to the lower angle of the wound, and the peritoneum being closed from above downwards, is carefully stitched about it with catgut. (Fig. 1.) The fascia and muscle are then closed and brought about the stump in the same way with the same material. (Fig. 2.) Two heavy silk-worm sutures are now passed through all the tissues of the abdominal wall, traversing the stump just at the peritoneal connection. (Fig. 3.) These serve as anchors and are essential aids to such other silk-worm sutures as are needed to properly coaptate other parts of the abdominal incision. Before closing the wound all excess of tissue in the stump is cut off flush with the abdominal fascia. Catgut sould be used throughout, reinforced by silk-worm gut in the abdominal wall as above stated. The sutures used as anchors should not be removed before the tenth day. Such patients should remain in bed four weeks, and be promptly fitted with an abdominal support on rising, the more pendulous the abdomen the greater need for this support.

Before closing, I wish to say a word against vaginal hysterectomy as a remedy for procidentia. It is too radical for partial prolapse and not sufficiently so for complete. In the latter deformity it removes the weight of the uterus but that is all, the attempt to utilize the round and broad ligaments as supports by transplanting them to the vaginal stump is fallacious, for they so soon atrophy, their efficiency is quickly annulled. Some have supposed that in addition to fastening the stumps of the round and broad ligaments to the stump of the vagina, were they to take a reef in the uterosacral ligaments, the requisite support would be obtained, but it is well to remember that owing to their relation to the rectum and proximity to the large uterovaginal plexus, they do not tolerate reefing well. Upon the whole the above operation is superior, and as soon as it is freed from the possibility of hernia, it will remain so far superior to every other device, having for its purpose the aiding and abetting of repair work at the pelvic floor, operators will make no mistake in employing it.

7 East Thirty-sixth Street.

## THE STUDY OF THE BLOOD IN RELATION TO THERAPEUTICS.

By E. CASTELLI, M.D., L.M. (Rotunda Hosp. Dublin).

NEW YORK.

CORRESPONDING MEMBER OF THE ASSOCIATION OF THE MILITARY SURGEONS OF THE UNITED STATES, MEMBER OF THE MEDICAL ASSOCIATION OF THE DISTRICT OF COLUMBIA, MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, MEMBER OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK, CHEVALIER OF THE RED CROSS, . . . . PATHOLOGIST TO THE BENEVOLENT INSTITUTE.

*The future of medicine belongs to hematology*—this was the sincere warning given many years ago to the seekers of medical progress by one of the most eminent hematologists of our day. It has been this strong conviction that has guided Professor Hayem of the faculty of Paris in his serious attempts to shed light upon the fields of pathology and therapeutics by studying the blood, and I, myself, have for a long time considered that the solution of the most difficult problems of medicine belongs to-day to hematology.

Our organism, notwithstanding its complexity, is composed of a mass of small organisms, each one having a life of its own; and it is necessary to study the living protoplasm in its specific and nutritive properties, in order to acquire in part the knowledge of the function and in part the knowledge of the pathological process. But the elementary bodies constituting the organism are connected to form a physiological entity, *"le moi physiologique,"* in such a way that the conditions of life of each element reside in the preexistence of a constant relation between one element and the others.

Two great systems preside over the harmonization of all the individual lives in order to assure the life of the whole, the nervous system and the irrigatory system. The importance of the nervous system does not need demonstration; the regulation of general circulation, of local circulation, of thermogenesis; the trophic influence on the nutrition of the anatomical elements, the stimulation of secretions, etc., etc., are all functions of the nervous system. But we can say that while these facts are so important in physiology they are of little importance in pathology, because the nervous disturbances involve a very limited number of processes. The pathology of the nervous system is essentially descriptive and its affections though interesting through the character of their systematic expressions, have no more value in nosology than those of any other organic system. But the relations established between the different parts of the organism have a main importance from a pathogenic standpoint. The incessant flow of blood of a certain chemical and morphological composition is the essential condition of the life of cells; any element of the body deprived of blood dies, and changes in the chemical and morphological composition of the blood create a condition of *functio læsa* of the constituting elements of the body as single physiological entities, and of the body as a whole; conditions whose ultimate effects may give rise to death. The blood carries with itself the oxygen and the material for the renewal of the protoplasm and rids the cells of the waste products that they much eliminate in order to be able to live. This complexly organized liquid is then continually changing, not only because of its chemical principles, but because its morphological elements are incessantly destroyed and incessantly replaced with

new elements. This destruction and renovation are the consequences of the great rôle played by the blood in the intraorganic changes.

The blood contains then in itself the principles of life and the principles of death of the organism. If such is the case is it strange to think that the future of medicine belongs to hematology? What have we done in order to discover the physiological and pathological secrets constituting the life of this complex element? Do we know what is the relation existing between the condition of the blood and disease itself? *Is it rational to think that each pathological condition must reflex itself in the condition of the blood, or that, perhaps, it is the condition of the blood that determines the disease itself;* it is a pathological axiom that rationalism confirms, although science has not yet demonstrated it. In the blood, then, we may find causes and effects of diseases, but aside from such an idealistic conception of the blood regarding it as the principal element of etiology and diagnosis, why do we not consider the blood as any other organ of the body and study it as such? When we talk about cirrhosis of the liver our already scientifically trained minds think of the anatomical substrata creating such a condition; we almost unconsciously think of the condition of the interstitial tissue of the liver, of the condition of its cells, bile ducts, and vessels, and it is natural for us to do so. But do we ever think that the blood plasma is nothing else but interstitial tissue surrounding and keeping together the morphological blood elements or cells? Do we ever think of the anatomical condition of the blood plasma as interstitial tissue? We have not in it, of course, either connective-tissue cells, or elastic fibers, but we have an infinite number of chemical elements, whose increase and diminution constitutes an anatomical substratum much more important from the pathological standpoint, because the variation in this anatomical substratum will not reflect its consequences on a single organ, but on the entire organisms. Do we ever consider the variation in the density of plasma in different diseases, the amount of mineral salts, its alkalinity, its acidity, the amount of oxygen contained in it, and its relation to the pathological conditions of the organism? Our experiments on the plasma and the chemistry of blood remain so far physiological experiments, not applicable to pathology, and besides the physiologist generally does not consider it worth while to spend too much time on such researches. We have studied the morphological condition of the blood, its cells, etc., it is true, and we know a great deal about them. Since Virchow has explained to us the existence of phagocytosis we have considered the blood, we have discovered that leucocytosis is a reactive process; that poikilocytosis is a process of necrosis; that hemoglobin constitutes the vital element of the red corpuscles, and so on; but have we really applied all this knowledge so systematically to our diagnostic researches as to make it an integral part of our diagnostic methods? In a few diseases we have found the necessity of examining the blood, and we keep on doing so, because the macroscopical evidences of the disease are so simple as to make the examination a very easy task. But to me such an attainment has the same value that the examination of the urine would have in clinical chemistry, if we should limit our researches to the detection of albumin by the boiling test, and consider ourselves satisfied with the result as the best and most satisfactory. We have also studied some chemico-organic reactions of the blood in typhoid fever; the power of agglutination has been taken as an element of diagnostic value. I remember many years ago in an epidemic of typhoid fever, while assistant in a hospital, to have made about 200 Widal reactions, but it was a great surprise to me to notice that often in the most severe cases the reaction failed, while in mild cases it showed a remarkable activity. But what was more surprising to me, was the fact that in cases absolutely non-typhoid I could detect the same reaction! Does such an experience destroy the value of the Widal reaction? Is it useless because of its unreliability? No, such a reaction constitutes a symptom peculiar to certain diseases, and not to one alone and, if so, it is a very important factor in diagnosis because it constitutes one of the elements of nosology. Why should we think a piece of pathological evidence to be always specific of a disease when found in the blood, while we do not think so when found elsewhere? It is the number of symptoms put together and their reciprocal relation of cause and effect and genesis that constitute diagnosis. If diagnosis should prove such a simple matter, it would be very easy to be a good physician. Following the same principle, why do we not say that albumin in the urine is a sign of Bright's disease; that glycosuria is the evidence of diabetes: that amenorrhea means pregnancy; that an acute retrosternal pain means angina pectoris; that dyspnea is an evidence of pneumonia, and so forth?

If we do not consider rational such a clinical proceeding why should we consider a single isolated pathological fact noticeable in a complex organ as the blood is, as a sufficient element of diagnosis, and of indisputable value?

There is fresh in my mind a case to which I was called in Washington three months ago. The patient, a lady, had been under my care while practicing in Washington; she was taken suddenly ill, and a colleague, whom I respect and consider, took charge of the case, but her general condition getting very unsatisfactory and the family feeling very much worried, they decided to call in two more physicians. Her condition did not improve, and the family finally asked the physicians to make a decisive statement about the condition and the prognosis of the case. The statement was made and was: Cancer of the cecum, surgical intervention the only resort. After such a statement the family decided to send for me. I went to Washington. I saw the two physicians upon my arrival, and we discussed the case before seeing the patient, examining the charts accumulated during twenty days through the activity and zeal of my colleagues. To my great surprise the blood examination was considered by the physicians to be the confirming element in their diagnosis of malignant tumor. The blood examination had shown the existence of a leucocytosis ranging from 8,000 to 14,000 leucocytes per c.mm. at different times, and this fact, together with other clinical symptoms, had brought the physicians to the conclusion. In cancerous affections they teach us that leucocytosis is always present, it is true, still diagnosis, we must remember, is a process of synthesis whose conclusions we reach after having correlated the different symptoms detected. I took the temperature chart and the blood chart together, and it was strikingly evident that to the maximum of temperature corresponded the maximum of leucocytosis, and to the days of normal temperature the minimum of leucocytosis (8,000). Can we make diagnosis of cancer under such circumstances? In this case the leucocytosis was a reactive one, proof of an inflammatory process started in the organism. The patient had had an attack of acute cystitis, with fever and severe pains radiating from the pubis to the region of the cecum, and the so-

called tumor was caused by a marked fecal stasis. It is not the first time that a disconnected detection of symptoms leads to the most erroneous diagnostic conclusions. I remember one of the most eminent clinicians known to-day to have diagnosed a plain case of podagra as a tumor of the cerebellum simply because he had detected in the patient the movement of retropulsion "pathognomonic of tumor cerebelli." It is an every-day occurrence, and we must not for that reason so readily criticise the mistakes made by our colleagues. We too often hear physicians harshly criticising, in the presence of patients, what has been done by others, and I have noticed it in some consulting physicians. It is due, of course, to lack of everything, but principally to lack of sense.

Diagnosis is a work of synthesis. We all can detect symptoms; the real difficulty consists in correlating them as causes and effects. To me the blood itself, with its manifestations, is the connecting element of symptomatology, as it is physiologically the connecting element of all organic functions. But what we want to do in discussing the study of blood is not to convince anybody of the necessity of studying hematology, but to draw from the little knowledge we already have some useful applications for practice. As any American does, I believe in the practical application of knowledge, and all this display of theories would not mean anything if I did not come to some practical conclusions. I think that while at present we do not know enough hematology for diagnostic purposes, we do know enough to be able to make practical applications of our knowledge to therapeutics. I want to remain in the field of logic, setting aside all views of theoretical nature. I only want to repeat what two years ago, as a representative of my own government, I said at the twelfth annual meeting of the Association of Military Surgeons of the United States, that was held in Boston on the 19th, 20th, and 21st of May, 1903:

"As I have remarked before, blood and lymph are the bearers and transmitters of any infectious element, and the localization of the infectious element, in a special organ or region of the body, is a simple process of metastasis. The microbes, or toxins, are transported by the blood vessels into such regions of the body as offer conditions most suitable for the accomplishment of their reactive processes, just as in a similar manner cancer cells are transported to those parts of the body wherein may be reproduced the malignant growths from which they themselves originated. Now, if our therapeutic agent should follow the same route as that followed by the infective element, its action, general and local, would take effect at such points as presented a necessity for its action. Thus we may confide to the blood our curative agent, while the question to be understood is—what curative agent is preferable? . ."

As you see, my pathological views blend with the physiological ones, and my therapeutic views are a direct consequence and emanation of my convictions. The therapeutic element must be confided directly to the blood in order to be carried to the spot where the source of infection is, so to act as a general neutralizing agent to the heterogeneous toxic elements causing the disease and contained in the blood. Also for that reason I prefer to refer my views on the same subject to the lecture held in Boston:

"To my understanding, disease is a closed wound in which the colonization of microbes and the action of toxins accomplish their destructive work far from our control. The therapeutic equation to be resolved is the same as that resolved by surgery, with the difference that to the term local antisepsis must be substituted the term general antisepsis, and I regard it as a singular thing that we physicians, with the fact in evidence before us, will too often lose time in trusting to the effect of our prescriptions, while we already treat successfully by direct injections of therapeutic agents in the blood, syphilis, malaria, diphtheria, puerperal fever, and many other diseases.

"These facts demonstrate that internal antisepsis is the basis of therapeutics, and that the blood is the clinical excipient of therapeutic elements, and being the bearer and transmitter of all toxins, endogenous and exogenous, assimilated from the organism, it follows that we may confide to it curative agents whose therapeutic action will reach the most remote regions of the human system, regions beyond the reach of the knife, or any other remedial agent. Modern therapeutics must ask of its sister sciences, bacteriology and chemistry, a study of the chemical reaction of the blood in the different diseases, and in this way discover the therapeutic agent which, introduced into the blood, may neutralize the toxins in the circulation. Of course, in this respect the term antisepsis possesses a broader signification, and its meaning becomes defined as that of a neutralizing agent of the heterogeneous elements causing disease."

So my practical point notwithstanding the lack of knowledge of hematology, is to take as an axiom that *in the blood we find the causes or the effects of disease in general and in consequence we may be able to eliminate the cause or counterbalance the effect of diseases by treating the blood entirely.* The problem is one of chemistry and a very delicate one on account of the accuracy required for its application. My intention is to sketch in a future paper my views on intravenous and hypodermic therapeutics, in different diseases and their results. I believe, frankly, that hypodermic and intravenous treatment must gradually replace the internal one. The reasons are so many that only a discussion dedicated exclusively to the argument can show the main points of my assertion. Our therapeutics is still in its empirical state, and this is the reason why quackery exists.

Such a condition of things naturally brings discredit on the profession, and lack of confidence in the patients, who easily reason and think that, if medicine is a science the discrepancy in such a vital question as the one of treatment means ignorance in somebody. The day in which we shall make therapeutics a mathematical science, and use drugs with more rationalism in their application, the victory will be ours.

201 West Seventy-fourth Street.

## A FEW PRACTICAL POINTS IN PEDIATRICS FOR THE GENERAL PRACTITIONER.*

By THERON WENDELL KILMER, M.D.,
NEW YORK.
ASSISTANT ATTENDING PEDIATRIST TO THE SYDENHAM HOSPITAL.

What the requirements of the general practitioner should be along the line of pediatrics, is a question that is rather difficult to answer. But as the clientèle of the average practitioner of medicine contains of necessity many infants and young children, it may not be amiss to enumerate several points with which I deem it wise for the general practitioner to familiarize himself in order that he may be better prepared to treat his little patients skillfully and understandingly.

*Read before the Bridgeport Medical Society, Bridgeport, Conn., on June 6, 1905.

Some physicians do not like children. They object to their crying and noise, and claim that they are unable to think at all while the child is making such a rumpus. There are three classes of children that the physician is called upon to treat. 1. The good child, one that seems to enjoy being examined. He will play with you and will keep quiet while you are examining him, and will make absolutely no fuss at all. You are in luck when you have such a child for your patient. 2. The nervous child, the excitable child, a child possibly who has been operated upon for adenoids without anesthesia, with the promise that it would not hurt him; a child possibly who has been ill much of his life and whose nervous system is in an irritable state. With this class of children we must take our time in examining them; it will not do to take out our stethoscope and hold the child while auscultating his chest. We must proceed cautiously. Let him handle your stethoscope; let him see for himself that it will not hurt him. Gradually gain his confidence, and do not abuse it after he has given it to you. Why is it that nine out of ten children are afraid of a doctor? It is because the parents usually hold up the doctor to the child as the "bogie man"; if the child is cross, or cries, the mother or nurse tells him if he don't look out the doctor will catch him and cut off his ears! So that about as soon as an infant can use his brain at all, he is schooled into the abominable trait of fearing the family physician. On the other hand, we ourselves are possibly responsible for the fear exhibited by our little patients. How many times have we lied to these babies of our clientèle, gaining their confidence by all the alluring promises of "It won't hurt you," and story-telling, and then, when these babies have opened their little hearts to us, given us their confidence and believed us, we plunge a knife into an abscess, or vaccinate them. We have lied to them; they know it, and will never forget nor forgive. Fancy trying again to win their confidence! It can never be done. 3. The third class of child comprises the vicious child, the spoiled child, a child who has never been crossed in a single wish or desire during his entire life. He has ruled the family from the time his occiput first traversed the perineum. These children will kick, bite, and scratch anyone who tries to interfere with their wishes. They are bad—not from any fault of their own; they have their parents to thank for their nasty disposition. With these children the examining physician should waste no time. It is love's labor lost to argue, coax, or talk to them. We must simply do our work from the beginning and let them know that we intend to examine them, no matter how much fuss they are going to make about it. We do not consider them a moment, do not talk to them, nor have anything to do with them, except what it is our business to do. It is surprising to see the change that comes over these fondled, spoiled pets of the family after a few examinations by the family physician, when the child finds out that no harm is meant to him, and that although he can rule the entire family, he can gain nothing by acting badly toward you. So, then, you see that, given a child to examine, he must of necessity fall under one of these three heads and we must deal with him accordingly.

There are three points which must be carried when we train an animal, whether it be a horse or a baby, and these points are: 1. Respect. Our patient must respect us and our wishes. 2. Confidence. They must place themselves wholly in our hands and trust us. 3. Obedience. They must do as we tell them.

*History.*—A brief history of the case is always essential. It is my rule, before seeing the child at all, to get the history from the mother or nurse in her own words, for if she is in the presence of her crying offspring her thoughts as to antecedent events are anything but clear. A history of the parents as to heart disease, rheumatism, or consumption should be elicited. The food of the infant or young child should be inquired into at length.

Having your history, you are ready for the examination. If you do not know the child, ascertain his or her first name, as there is nothing that inspires confidence in a child more than entering the room and saying, "Hello, Tom!" or "Hello, Julia!" Proceed as though you had known them all your life. Children make snap diagnoses of their attending physicians, and, as soon as you enter a sick room the child either likes you or does not like you; so it depends upon how you carry yourself during the first two minutes whether he is your friend or your enemy. Treat a child as though he were a human being. Sympathize with him if necessary, play fair with him, use no deception. If you are going to hurt him, tell him so; win his confidence by straightforward methods. There is all the difference in the world between a man who loves children and a man whom children love; and the highest tribute to the character of a person is that it may be said of him "children and dogs are fond of him." So much for digression.

*Physical Examination.*—In the physical examination of an infant or young child, one thing is important, and that is to have the patient undressed, naked. Many a skin eruption is overlooked by the physician's not adhering to this rule. No matter what the complaint is, undress your patient. There are physicians who claim that they can auscultate an infant's chest satisfactorily through the clothing—I cannot. If your patient is crying when you first see him, it is wise to take the temperature—by rectum—first; if he is quiet when you first see him, his chest should be auscultated first. If you are called to a case where the parent informs you: "Doctor, my baby is asleep; shall I awaken him?" answer by all means, "No." Inspection of a sleeping child is often well worth hours of handling. Notice his respiration; is it rapid, quiet, or labored? Is he cyanotic? Do the alæ nasi dilate at each respiration? Is his respiration abdominal or thoracic? Does the child twitch? Is there any paralysis? Is the head retracted? Is there obstruction to inspiration or to both inspiration and expiration? Does he moan from exhaustion, or cry out sharply occasionally from pain, or is the cry continuous? All the above and many other points of interest to the examining physician may be ascertained by simply cultivating the power of observation.

The stethoscope is of paramount importance in the auscultation of an infant's chest. The one I show you is at present used by many pediatrists and has a small bell made of aluminum. Some physicians prefer the ear for auscultatory purposes in the examination of infants and young children—but for just one moment—what a fallacy this is! If in an infant's lungs there should be a spot of consolidation as large as a quarter of a dollar, how many, think you, would diagnose the case correctly of those who use the ear against the chest wall? Not one in ten, because the average adult ear would cover almost the entire lung of an infant. Then, again, the ear does not fit closely enough to the skin to exclude air and extraneous sounds. Do not make the mistake in a case of pneumonia in putting the mustard plaster on the wrong side, a mistake which may happen owing to the fact that more noise is made by the sound lung, which is doing all the work, and this loud, exaggerated breathing is often mistaken for bronchial breathing, while the affected side, showing diminished, high pitched, or bronchial breathing

escapes unnoticed. It is neither pleasant for the consultant, nor for the attending physician, when a case has been blistered and poulticed on the left side, to find the real cause of the trouble on the right side. When an entire chest, front and back, has bronchial breathing over it, it is almost pathognomonic of fluid in the chest. This is especially so after an illness has been going on for some time.

How are you going to obtain an infant's sputum in a suspected case of tuberculosis? The method employed for obtaining sputum from babies is to pass a catheter, 21 F., into the esophagus, as the act of gagging forces the sputum, which is in the esophagus, into or on the catheter. The catheter is withdrawn, sealed in a large test tube, or bottle, and sent to the pathologist for examination.

In examining a baby you must rid yourself of all adult anatomy, diagnosis, and landmarks, as they are usually a stumbling block to the student of the baby, who is an entirely different proposition. If you try to locate with your finger the apex beat of the heart of a baby in the usual place laid down for adult heart beats, you will not find it. It is impossible to locate the apex beat in an infant or young child, except by the use of the stethoscope. The apex beat is normally found in a child up to the fifth year to the left of the nipple line. In an infant the heart is almost in a horizontal position in the chest, and gradually swings over into a semi-upright position as the baby grows older.

Congenitally diseased hearts should be examined for in every infant a month after delivery, as it is a most unpleasant thing to be called in consultation and find a congenitally defective heart in a baby which the obstetrician pronounced perfect. These cases occur and act as boomerangs. The abdomen should be palpated in every case. The liver is normally slightly below the level of the ribs in babies, but a spleen that can be palpated at all is considered enlarged.

Tumors caused by impacted feces, intussusception, appendicitis, and enlarged retroperitoneal glands should be palpated for in examining the abdomen.

The throat should always be examined when you are called to see a sick baby. The diagnosis of scarlet fever may oftentimes be confirmed by an examination of the throat; given a child with a rash which resembles scarlet fever and a throat that is pale, it is pretty certain that the case is not one of scarlet fever.

In chronic coughs with negative chests always examine for adenoid growths. Never operate for adenoids without an anesthetic for three reasons: 1. You cannot do a thorough operation when a child is conscious. 2. You at once make that child your enemy for life, and future examinations are difficult. 3. The nervous shock to the system of a child who is suddenly and forcibly held by a nurse or physician who says he is not going to hurt him and then pries open his jaws, introduces a forceps or curette, scrapes his nasopharynx, causing blood to flow out of the nose and mouth; I repeat that the nervous shock to a child who is thus treated more than counterbalances the danger of a properly administered anesthetic. Never promise the parents, after you have done an adenectomy, that the growths will not return, because they may recur in the course of a year or so, and then discredit will be placed on you by the family. I have seen cases which are regularly operated on every two or three years, and at each operation a large mass of adenoid tissue comes away, after which, upon digital examination, the nasopharynx will be found to be clear. Always examine your adenoid cases a month after operation by placing your finger in the nasopharynx and breaking up any existing adhesions which might later cause all the symptoms of adenoids.

A set of ear specula and a head mirror should form a part of the general practitioner's daily armamentarium. The ears should be examined in nearly every case, especially where there is fever, with the same frequency and ease as one examines a throat. Many a case of continued fever in children is caused by a bulging ear drum. During the past two years I have had many cases of this class, and in the majority of them the attending physician had been doing his utmost to control the fever by the use of quinine, meanwhile having repeated negative examinations made for the Widal reaction and for the malarial parasite; an incision of the ear drum caused the symptoms of malaria, paratyphoid, and chronic grip to cease immediately.

We are now passing through an epidemic of cerebrospinal meningitis, and there are many cases of other diseases with cerebral symptoms diagnosed as true cases of cerebrospinal meningitis. Do not make a too favorable prognosis in your case of cerebrospinal meningitis, as notwithstanding the comparatively low mortality in this disease reported by some observers, I regard it, especially in this epidemic which we are now undergoing, as having a very high death-rate. Given a baby with symptoms of cerebrospinal meningitis, a brain and spinal cord thickly coated with pus, either from the meningococcus, pneumococcus, or other bacterial infection, it is with the greatest rarity—if ever—that such a case recovers. In severe grip infections, in pneumonia, and diarrhea, we often see cerebral symptoms which almost entirely mask the real diagnosis, and these cases are erroneously put down as cases of cerebrospinal meningitis.

In a child under two years of age always have your doubts when the parents inform you that the child has rheumatism. Examine his gums, and you will usually find it to be a case of scurvy. It is surprising to see these so-called cases of rheumatism get well in a day or so, when placed upon a proper diet and orange juice.

In cases of malnutrition in young children, when you have exhausted all your methods of treatment, such as hygiene, feeding, etc., always suspect syphilis. Place those children on a "tonic" of bichloride of mercury and idodide of potash, and see them respond to it at once.

The man has never lived who can look down a throat with an exudate in it, and pronounce positively that it is or is not a case of diphtheria. I therefore beg of you to use your antitoxin early and in large amounts. When in doubt, use antitoxin. Far better is it to use antitoxin in cases of tonsillitis and have a live baby, than not to use it in a case of diphtheria and have a dead baby. I have many times injected antitoxin in a suspicious case and afterwards, by bacteriological culture, have had it prove to be one of simple tonsillitis, but no harm was done by the injection. Use your antitoxin early and fearlessly, and your diphtheria mortality will be low. Any parent or physician who, in the face of the marvelously beneficial results attained by the use of antitoxin, refuses to allow the use of, or refuses to use, antitoxin, has no right to have children nor to practise medicine.

In every case of diarrhea stop all milk immediately, give a dose of castor oil, and feed the patient on plain boiled water, or some form of cereal water. Resume milk very gradually.

*Feeding.*—The successful feeding of infants and young childen comprises nearly one-half of the practice of the average pediatrician. The general practitioner should know more than he usually does about

the feeding of the rising generation entrusted to his care. True, a general practitioner cannot be a children's specialist and still keep up his general practice, but, nevertheless, he should have fixed in his mind (not his pocket) what a baby has a right to demand. An infant has a right to demand mother's milk, which contains fat, proteids, and sugar. If he cannot obtain this food, it is the physician's duty to see that he gets some kind of food that contains approximately the amount of fat, proteids, and sugar which mother's milk contains. This is the nutshell of successful infant-feeding. But even though this be a simple matter, how many physicians who are in general practice and who are feeding many babies can tell you how much fat, proteids, and sugar there is in the average woman's milk? How, then, can these same men successfully feed babies when mother's milk fails? Formulas in the pocket are a poor substitute for common sense in the brain. Formulas are for well babies, and supply a demand for a comparatively easy, though not always, correct way to feed them. No two babies can be fed by the same rule. Therefore, we see the fallacy in depending too much upon set formulas. Each baby should be fed as an individual and not as one of a certain class of individuals. The so-called scientific feeding of infants, where the student or general practitioner is confronted with page after page of algebraic characters, is enough to discourage the best of us, and after wading through "let x = the amount of proteids, and y = the total amount of cream removed by the second dipperful from the top of a quart bottle of milk," the seeker for knowledge is apt to close the book and exclaim: "If this be the scientific feeding of infants, it is too complicated for me."

The most simple and practical method for feeding babies is the one taught and practised by Dr. Charles Gilmore Kerley of New York City. It was first published in the MEDICAL RECORD of August 31, 1901, and is based upon the fact that cow's milk contains practically 4 per cent. of fat, 4 per cent. of proteids, and 4 per cent. of sugar. Therefore, the following dilutions, taking the pint as the unit of measure, are self-evident:

| | Fat. | Proteid. | Sugar. |
|---|---|---|---|
| 8 oz. milk, 8 oz. water | 2. | 2. | 2. |
| 4 oz. milk, 12 oz. water | 1. | 1. | 1. |
| 2 oz. milk, 14 oz. water | .5 | .5 | .5 |

Gravity cream contains

| | Fat 16. | Prot. 3.2. | Sugar 3.2. |
|---|---|---|---|
| Therefore— | | | |
| 1 oz. cream, 15 oz. water | 1. | .2 | .2 |
| 2 oz. cream, 14 oz. water | 2. | .4 | .4 |
| 1 oz. cream, 2 oz. milk, 13 oz. water | 1.5 | .7 | .7 |
| 2 oz. cream, 2 oz. milk, 12 oz. water | 2.5 | .9 | .9 |
| 2 oz. cream, 4 oz. milk, 10 oz. water | 3. | 1.4 | 1.4 |
| 3 oz. cream, 2 oz. milk, 11 oz. water | 3.5 | 1.1 | 1.1 |

Now, with these two facts in mind, namely, knowing what whole milk contains and what gravity cream contains, we can mentally make any strength of mixture we desire by simply diluting our milk with water until we get the percentage of proteid that we wish and then adding cream until we get the amount of fat that we wish. Milksugar or canesugar is added to supply the deficiency in sugar; in round numbers, an ounce of sugar to a pint of mixture adds 5 per cent. to that mixture. Two one-quart bottles of milk are necessary for the feeding of babies according to the above method. The cream is removed from one bottle and stirred to insure its uniformity of 16 per cent. fat. The other bottle is inverted several times thoroughly to mix the cream with the milk and to insure its uniformity of 4 per cent. fat, 4 per cent. proteid, and 4 per cent. sugar.

Absolute percentage accuracy is not claimed for the above method, but it is near enough for all practical purposes, and gives the general practitioner an idea of the nutritive values of various combinations of milk, cream, water, and sugar. It is always well to begin in a young infant by giving a low protcid, say, 0.5 per cent., and gradually increasing it to 1.5 per cent. when six months of age.

| | Fat. | Prot. | Sugar. |
|---|---|---|---|
| At birth | 1.50 | .5 | 6. |
| Gradual increase of all ingredients up to: | | | |
| At 6 months | 3. | 1.50 | 7. |
| At 12 months | 4. | 3.00 | 6. |

In keeping track of feding cases there is nothing so essential as a record of the correct weight, daily at first, then weekly. In all my feeding cases I supply the mothers and nurses with blank reports, such as the following:

Date.....19

Name. Age.

1. Weight...lbs..ounces. Loss / Gain } since last report

2 Stools: Frequency and general character.

3. Vomiting or Regurgitation: When? How much?

4. Flatulence or Colic. When?

5. Appetite. Is the baby satisfied? Does he leave any of his food?

6. How often is he fed? Quantity each feeding?

7. Is the baby comfortable and good natured?

8. How much does the baby sleep?

9. How long each day is the baby out of doors?

10. Other notes of interest:

Date of last report.....19..

Baby at present is fed on the following food:

These blank reports are filled out by the mother or nurse and returned to me weekly or monthly, so that, no matter where the baby is, I have him under observation and can tell at a glance whether he is progressing favorably. This method of reports is strongly advocated by Dr. L. Emmet Holt, and is certainly of great help to both mother and physician.

It is important that the infant should be fed proper food from birth until he is twelve months old, but just as important is it that he should receive proper nutrition from the first to the sixth year. For the benefit of parents and nurses I have had slips printed showing the foods which should be given an average healthy child from the second to the sixth year.

It is not my intention to prolong this paper into a book on pediatrics, but simply to enumerate a few practical points and suggestions that have been of great service to me during the past ten years of work among children.

165 WEST EIGHTY-FIFTH STREET.

## DEAF-MUTISM AND PTOMAIN POISONING.*

BY W. SOHIER BRYANT, A.M., M.D.,

NEW YORK.

THE causes of deaf-mutism are often obscure. Any elucidation of these difficult cases should be of general interest. These cases also suggest the possible origin of certain other obscure nervous and mental conditions.

CASE I. Our first patient was a girl, two years and seven months old at the time of the poisoning. Her previous history was given by her father and mother and confirmed by her doctor and others. She was well, lively, talkative, very bright, and played like other children. One year previously she had

*Read before the American Otological Society, 1905.

had an attack of doubtful measles. Her family history was negative. She was an only child. Her parents had been married five years. By a previous marriage the father had several other children who were grown up.

On March 23, 1903, the patient was taken sick after eating ice cream which was bought of a street vendor. She had high fever, and on the next day was taken to the German Hospital, Brooklyn. Her hospital record was as follows: pulse 124; respiration, 28; temperature, 101.2°; diagnosis, acute gastroenteritis, and later, ptomain poisoning; treatment, spirits of turpentine. On March 25, the urine was normal and the temperature 102.3°.

On her return home, after four days, she did not walk well. At first her legs seemed "partially paralyzed." For six weeks she staggered and grasped at objects to steady herself. She had difficulty in drinking, and had spasms of either one side or the other of the face. By signs she showed discomfort or pain in the head. Her father first noticed her deafness about one week after the poisoning; it was then total.

About one month before I saw the patient she was operated upon for adenoids. When examined May 5, she spoke no words, but made inarticulate sounds and signs. She was pale and sallow, and fairly well-nourished. All her teeth were present, and well-formed. There were no signs of rickets; no enlarged lymphnodes. The alæ nasi were slightly ecorciated. There was nasal breathing. She looked drowsy, and appeared fretful, timid, and suspicious. She walked unsteadily, with feet far apart. There was no atrophy of the muscles nor any evidence of paralysis.

The ear showed nothing peculiar about the auricle or external meatus. Both drum heads were slightly retracted. The light reflexes were small and bright. The color of the membrane was slightly darker than the normal color. The child appeared to hear no sounds and did not respond to any noise, but noticed quickly a loud knock on the floor, or a jar sufficient to shake the room.

On July 13, the condition of the ears was unimproved. The child was fretful. Her physical condition was not quite so good as before. Although her general condition was still poor on August 16, there was some improvement. The right drum head was dark. There was no light reflex. Nasal breathing. The pharynx was anemic, but otherwise normal. The treatment prescribed was four grains of iodide of potassium, three times daily. On April 10, 1905, the condition of the child was practically unchanged.

The association of the paretic symptoms with the gastroenteritis which preceded them indicates their toxic origin, and, together with the history of the street ice cream, furnishes evidence that the poison must have been some ptomain.

Case II. In the second case under consideration, the data are few, but suggestive. The patient was a boy, two and one-half years old. Seven weeks before I saw him, he had an attack which his parents described as "fever." No physician was called. For four weeks after this attack the child could not walk, and he did not hear for some time. He now hears only a very loud voice. Inspection of the ears showed no abnormality.

I find the literature on this subject very scarce, and have attempted to fill the gap by using the literature on eye affections which follow ptomain poisoning. It does not seem too far-fetched to draw an analogy between the affections of the visual and those of the auditory mechanism. It seems sufficiently reasonable that the changes in the two sensory nervous systems occurring from the same poison are practically identical in their pathology. For this reason I have taken the liberty of quoting from authors writing on the subject of ptomain poisoning with eye symptoms. I am especially indebted to Ritzke.[43]

In 1817 Justinnus Kerner described eye symptoms in botulismus, but mistook it first for trichinosis. Since this time many authors have written on disturbances of vision from ptomain poison. The cases described were produced by many varieties of food, meat, fish, fresh or preserved, and dairy products, etc. The symptoms referable to the eye begin some time after the onset of the symptoms of poisoning. The symptoms are both motor and sensory. The eye symptoms are mydriasis, decrease of vision, ptosis, and defective accommodation. Most of the patients with eye symptoms soon recover. The rest, a very small number, die.

The affections of the eye were bilateral. The eye symptoms were what caused the patient to seek medical assistance. They came on later than the other symptoms of poisoning, in from one, eight, nine, to ten days. They were usually troubles of accommodation. In one case only, the latter were not present. Paralysis of accommodation was often the only eye symptom. This is the earliest symptom, and next appears the paralysis of the external rectus. As a rule, the degree of the paralysis is in proportion to the severity of the poisoning. Pupilary paralysis is less noticeable except in severe poisoning. Ptosis is the most frequent paralysis of the extrinsic muscles. One case of decreased vision was noted. Cohn[9] noted amblyopia; Guttman[23] found the eye grounds changed with hyperemia of the papillæ. Around the optic disc, the retina was gray and altered. Ruge[41] and Pflüger[25] mention conjunctivitis, keratitis, panophthalmitis and phthisis of the bulb. Dr. C. S. Bull will report three cases of choroiditis before the American Ophthalmological Society. The prognosis is good for a complete cure, in from two days to eight weeks. The accommodation paralysis which appears first, disappears last.

The symptoms are considered very similar to those of atropine poisoning, but differ in this respect that atropine in small doses affects first the pupil, and in large doses, accommodation, whereas the sequence is reversed in ptomain poisoning.

*Bacteriology and Toxicology.*—Van Ermengen[31] discovered the *Bacillus botulinus* in the spleen of patients who had eaten ham. He also found it in the ham. It appears that a specific toxin is produced by this bacterium. When used experimentally on animals, this toxin produces blepharoptosis, mydriasis, diplopia, dysphagia even to aphagia, obstipation, and retention of urine. The other forms of ptomain poisoning is attributable to *Proteus* and *Coli bacilli* and *Bacillus enteritides* (Gartner). The occurrence of early symptoms indicates that the poison was present before ingestion. Marinesco[32] experimented on the action of *Bacillus botulinus* on the nervous system. It caused cellular degeneration, first of Nissler's cells which became fewer with an increase of neuroglia. Kempner and Pollack[33] found that degeneration seemed to attack individual cells at first.

Tschernyschew[37] found on autopsy following death from fish poisoning, changes in the ganglion cells most marked in the medulla and least so in the cerebellum.

Römer and Stein[42] studied the effect of ptomain poisoning on the brains of monkeys. They found changes in the oculomotor nuclei and the degeneration most marked in the cells which Bernheimer considered the accommodation center. Nuclei in the neighborhood of the aqueduct of Sylvius were also

affected. Römer and Stein concluded that the accommodation paralysis of ptomain poison originates from a degeneration of the oculomotor nuclear centers, and that it was caused by direct action of the ptomain.

Ritzke[43] concluded from a study of 64 cases that the symptoms confirm the theory that the nuclei are the point of origin of the accommodation paralysis.

Neuritis can be caused in its various forms and locations by intoxication. Wittmaach,[44] in his article on the toxin nuritis of the auditory nerve and ganglia, reports a case of general intoxication with auditory neuritis. He states that auditory neuritis is analogous to optic neuritis and that their etiology is the same; also that the clinical symptoms and pathological anatomy are analogous. Unfortunately, ptomain poisoning (*Wurstvergiftung*) is not one of the causes he mentions.

Though there is such a scarcity of literature on our subject, a fair analogy can be drawn between the effects on the auditory and those on the visual motor systems. This enables us to picture the changes occurring in the organ of hearing after ptomain poisoning.

We have a clinical case of what appears to be auditory neutritis of toxic origin, and also toxic degeneration of the speech centers. The prognosis is bad, as no improvement has yet appeared.

Our case suggests the possibility that some of the cases classified under Ménière's disease may be in reality neuritis of the auditory nerve, and of toxic origin, possibly ptomain. We can also infer that ptomain poisoning may sometimes be the source of deaf-mutism and of deficient mental development as well as of various kinds of paralysis of obscure origin.

It is probable that ear affections following ptomain poisoning will be found more numerous when we are on the lookout for them, as it is not likely this poison is especially discriminating in its action in favor of the auditory nervous system and selective of the visual system.

It is reasonable to suppose that the acute deafness and vertigo in this case following closely on ptomain poisoning were the results of neuritis, either peripheral or central, consequent to the intoxication. The aphasia must be accounted for by some central degeneration. That the difficulty in deglutition was probably due to the involvement of the facial nerve together with the auditory, appears more probable because of the facial spasms.

In lieu of an autopsy, we may use the findings that have been published in eye cases of ptomain poisoning. These justify the inference that in our case similar degenerative changes had taken place in the auditory centers. It is also fair to suppose that the auditory centers were affected, together with the speech centers, as is shown by the aphasia present with the deafness. In addition we may infer that the disturbances of the facial nerve indicate a peripheral neuritis of that nerve, in which its neighbor, the auditory nerve, was probably also involved.

*Differential Diagnosis.*—I. Encephalitis of suppurative organ can be excluded by the absence of the history and a focus of infection. Chronic non-suppurative inflammation of the brain is excluded by an acute onset.

II. Atropine poisoning is excluded by the absence of eye symptoms or by their reversed order.

III. Cerebral hemorrhage or embolism is excluded on the ground that to include the variety of symptoms seen, the condition must be still more grave than we find in our cases.

IV. Cerebrospinal meningitis is excluded by the course of the attack. In cerebrospinal meningitis, the head symptoms are early predominant and spinal irritation is generally noted. In ptomain poisoning, which is usually a mixed infection, the abdominal symptoms are most marked at first, and the cerebral symptoms develop gradually Ptomain poisoning is generally ushered in by an attack of gastroenteritis, due to the mixed infection. In cerebrospinal meningitis, however, the first symptoms are of rhinitis and the cerebral symptoms appear early. In ptomain poisoning, the nervous symptoms appear late, without any spinal symptoms. Ptomain poisoning differs from non-toxic diseases in that it usually affects several individuals of a party simultaneously.

V. Acute bulbar paralysis is excluded if deglutition is not seriously affected, and also by the presence of paralysis of some of the anterior cranial nerves.

*Conclusions.*—Ptomain poisoning or botulismus is caused by specific *Bacterium botulinus*, which produces a specific poison, botulim. This toxin has a special selective action in the central nervous system, giving a more or less definite group of symptoms.

There are other bacteria which cause symptoms of gastroenteritis usually concerned in ptomain poisoning.

The diagnosis can be based on the history of the case and the sequence of the symptoms.

Botulismus may very possibly be the cause of many of the paralyses and nervous degeneration of obscure origin, and perhaps in some cases, the primary cause of arrested central or peripheral nervous development.

## SOME FURTHER NOTES ON THE TOXEMIA OF PREGNANCY.

By WILLIAM S. STONE, M.D.,

NEW YORK.

INSTRUCTOR IN GYNECOLOGY, COLUMBIA UNIVERSITY.

In a paper entitled "The Toxemia of Pregnancy" (*Amer. Gyn.*, December, 1903) the writer attempted to show that the vomiting of pregnancy is a manifestation of a toxemia, the lesions of which are primarily an acute degeneration of the liver, amounting to necrosis and destruction of liver cells in the severe cases, and presenting lesions in many of the fatal cases essentially those of acute yellow atrophy. The metabolism is imperfectly carried out as a result of these lesions, and various unoxidized compounds are formed in place of urea, which in themselves are more or less poisonous.

Further clinical study of this condition has more certainly convinced the writer of the truth of this opinion, and the clinical notes of the following cases, supplemented by some complete urinary analyses, may contribute in a measure to our still meager knowledge of the subject.

The urinary analyses were made in the pathological and chemical laboratories of the Cornell University Medical School, and I am indebted to Dr. James Ewing for the notes of Case III, for the clinical examinations of the urine, and for the privilege of examining the sections of numerous fatal cases. I am also indebted to Dr. C. G. L. Wolf for the determination of the nitrogen partition in the urines. The presence of leucin and tyrosin was determined by the following method: The albumen is first removed by boiling with acetic acid. To the filtrate one-half as much saturated solution of basic lead acetate is added. The lead is then removed from the filtrate by a current of hydrogen disulphide. It is then filtered and concentrated by boiling to a syrupy consistence, when the crystals are recognized from their characteristic shape and color. The total nitrogen was determined by the Kjeldahl method; the ammonia-nitrogen by the Schaeffer method of distillation in vacuo at 50° C.; the urea-nitrogen by (1) Folin in the urine itself, (2) in the phosphotungstic acid filtrate; the amino-acids by the Pfaundler method, the difference between the urea and the total nitrogen being taken as the amino-acids. Wolf considers that Pfaundler's method, when properly used, gives excellent results for clinical purposes, both with normal and pathological urines, and in every case in which a large percentage of amino-acids has been found leucin and tyrosin have been demonstrated in the urine itself.

The cases have been divided into two clinical groups, the first group including four cases of the pernicious vomiting of pregnancy, the second group including three cases of the preeclamptic type.

Group A, Case I.—Age 20; married six months. Menstruation had been normal, and she had considered herself in perfect health prior to the present illness, although she had always been careless about her diet and general hygiene. Vomiting began seven weeks after the last menstrual period, and becoming almost continuous within a short time, had persisted for four weeks. No physician had been consulted, but she had attempted to improve her condition by visits to Atlantic City and Lakewood. The writer's first observation revealed a serious condition. The patient was very thin and pale, and her face presented an anxious expression. Pulse 100 and feeble; temperature 99.5° F. The liver percussed, small, and could not be felt beneath the costal margin. These physical signs, however, are of doubtful value, especially in pregnancy, because of the gaseous distention of the intestines that is so frequently present. The uterus was enlarged to a size that corresponded with the menstrual calculation, and was sharply anteflexed, and in its normal position. The vomiting, that had begun to be black, persisted in spite of catharsis and saline irrigation of the colon, so that at the end of twenty-four hours the uterus was emptied under nitrous oxide and ether anesthesia. Vomiting ceased two hours after recovery from the anesthesia, and a rapid convalescence followed. The urine passed during the twenty-four hours preceding the operation showed the following: Amount, 700 c.c.; specific gravity, 1.025; faint trace of albumin; no casts; indican moderately increased; leucin and tyrosin present; urea by the hypobromite method, 3.39 per cent. A

determination of the nitrogen partition gave: total nitrogen, 6.237 grms.; urea nitrogen, 72.2 per cent.; amino-acids nitrogen, 1.4 per cent.; ammonia nitrogen, 1.23 per cent. Four days after the operation the nitrogen determination showed total nitrogen to be 6.003 grms.; urea nitrogen, 80 per cent.; amino-acid nitrogen, 1.6 per cent.; ammonia nitrogen, .49 per cent.

Case II.—Age 25. Married three years, with no pregnancy. Patient was very fat, had taken no exercise, and was a very heavy eater, especially of meats. Vomiting began five weeks after the last menstrual period, and had continued for five weeks, the last two weeks being accompanied by a burning pain in the epigastrium and excessive ptyalism. Slight jaundice had also been present for several days. Her mental condition was alarming, she at times threatening to kill herself. The liver could not be felt beneath the costal margin. The pelvic organs were normal, except that the cervix was of firmer consistence than is usual at this period of pregnancy. Pulse 110, of good quality; temperature 100° F. Saline irrigations of the colon, which were rather imperfectly carried out, caused no improvement, and at the end of four days the uterus was presumably emptied under ether anesthesia, but the vomiting continued after the operation, and an increase in the uterine discharge four days later, and the occurrence of a chill with a temperature of 101° F. suggested that the operation had been incompletely performed. A second intrauterine exploration under anesthesia revealed the presence of numerous gestation products, after a removal of which the vomiting ceased, although the patient's condition remained critical for several days. A urinary examination made before the first operation showed the following: Amount 545 c.c.; acid reaction; specific gravity, 1.021; no albumin or casts; marked sediment of urates; indican markedly increased; many leucin balls. A determination of the nitrogen ratios gave: total nitrogen, 5.17 gms.; urea nitrogen, 47 per cent.; amino-acid nitrogen, 22 per cent.; ammonia nitrogen, 2.5 per cent.

Case III.—Age 32. Had suffered from pernicious vomiting in three previous pregnancies, and from occasional attacks in the last one. Had been vomiting severely in the present pregnancy for two weeks, and was admitted to the hospital in a precarious condition on account of a threatened miscarriage at the sixth month. Death occurred in a few hours, and the autopsy showed an acute degeneration of the liver and kidneys. The urine was acid; specific gravity, 1.025; contained a distinct trace of albumin and a few hyaline and granular casts; indican considerably increased. The determination of the nitrogen ratios gave: total nitrogen, 0.26 gms. per 100 c.c.; urea nitrogen in the phosphotungstic acid filtrate, 23 per cent.; amino-acid nitrogen, 19 per cent.

Case IV.—Age 30. First pregnancy had been terminated in the latter months because of "acute Bright's disease," after which she was not in good health for a long time. Constant vomiting has been present for several weeks in the present pregnancy, which is now advanced to the third month. Fever has also been present during the past week. The patient was emaciated, and had a rapid and feeble pulse. The urine contained a trace of albumin, casts, and leucin and tyrosin. Saline irrigations of the colon did not improve the condition, and a bougie was introduced into the uterus without anesthesia. The uterus promptly emptied itself, but during the progress of the abortion the patient nearly collapsed, after which improvement followed. The fever, however, continued for several weeks, and treatment for typhoid fever was carried out, as the Widal reaction was positive. One year later patient became pregnant again, and the pernicious vomiting recurred, but the uterus was promptly emptied, and recovery rapidly ensued.

The individual symptoms in this group of cases merit some special comment. The appearance of black vomit in Case I, regarded generally as of serious import, and considered by the writer in his previous paper as a possible sign that the time for emptying the uterus has passed, shows that it is not necessarily of fatal significance, although the writer still believes its presence always renders the prognosis grave. The combination of symptoms in Case II—vomiting, ptyalism, jaundice, and serious mental disturbance—is rarely seen. Ptyalism has been referred to by the writer in his previous paper as a manifestation of toxemia, and a case was reported in which it occurred in two successive pregnancies, without, however, being accompanied by vomiting. The patient complained of more discomfort from this symptom than from the vomiting. The presence of jaundice in these cases has occasionally been noted, and naturally offers confirmatory evidence of the hepatic basis of the disease. The mental symptoms presented by Case II are of the greatest clinical importance, and should be carefully noted by those who find in hysteria a satisfactory theory for the origin of the disease. The first medical attendant of this patient evidently belonged to this persuasion, as from his remarks and treatment he evidently regarded these periods of mental distress as the expressions of a foolish and hysterical woman. The writer believes it is of the greatest importance to regard these mental aberrations as much a manifestation of the toxic process as is the vomiting. The maniacal delirium manifested as the patient recovered from the anesthesia after the second operation was so similar to that seen by the writer in a previously fatal case that he was inclined to think that an immediately fatal termination was inevitable. The persistence of the vomiting after the first operation furnishes an important lesson. Although portions of the fetus were found at the second operation, the presence of perfectly fresh placental tissue, which had evidently not been disturbed at all by the previous operation, might be regarded, in the light of Halban's recent work, as the part of the gestation product, if any, which is the source of the poison. Halban ("Die innere Secretion von Ovarium und Placenta und ihre Bedeutung für die Function der Milchdruse," *Arch. f. Gyn.* Bd. 75.353, 1905) believes the placenta to have an internal secretion similar to, but more active than, the ovary.

Case IV presented difficult problems in diagnosis and treatment. The positive Widal reaction would appear to have made the diagnosis of typhoid fever certain, but several observers have noted this reaction in the presence of hepatic diseases. Ludke (*Folia hæmatologica*, March, 1905, 182) noted that of thirty-six cases of liver disease, of which thirty-two had jaundice, the blood in nineteen agglutinated the typhoid bacilli in dilution of 1:20, and in eleven in dilution of 1:50. Although a high temperature is not an ordinary symptom of toxemia, the writer has noted its presence in several instances. The frequent occurrence of sepsis in these cases must also be remembered. The history of "acute Bright's disease" in the first pregnancy, the typical clinical course in the second pregnancy up to the time of the appearance of the fever, with the absence of other symptoms of typhoid fever, and the recurrence of the pernicious vomiting in a third pregnancy strongly indicate a common basis for all of these at-

tacks. The writer would also call attention to the method of terminating the pregnancy in this case by the introduction of a bougie into the uterus without anesthesia as one to be recommended in similar instances, in which the condition is so desperate that a rapid emptying of the uterus under anesthesia might prove fatal.

The study of the urinary changes in this group of cases shows the striking fact that the ordinary clinical tests furnish practically negative evidence of the presence of any serious disturbance. A diminished amount of urine, a practically normal specific gravity, a trace of albumin in two cases, a few hyaline and granular casts in the fatal case, the amount of urea, as determined by the hypobromide test in Case I, larger than normal, were the only evidences these methods furnished. Efforts to find an easily applicable method have so far been futile. Ewing has found leucin present in the urine of every serious case of the writer's, but he has also found it in two cases that so far have not proved to be grave, so that the significance of its presence must be still regarded as uncertain.

If a disturbance of the liver metabolism is the basic factor in the toxemia of pregnancy, it would be natural to expect that the normal ratios of the different forms of urinary nitrogen would be disturbed, and it will be seen from the table that such a disturbance is shown in all of the serious cases of Group A, in which the determination was made. The total nitrogen was markedly diminished in all of them, which is doubtless due to their limited diet. The urea nitrogen, normally running with a full diet from 80 to 90 per cent., is reduced from 72 per cent. in Case I to 23 per cent. in Case III. The amino-acid nitrogen has increased in Case II to one-half that of the urea nitrogen, and is almost equal to the urea nitrogen in the fatal case. The ratio of the ammonia nitrogen, however, was not disturbed, except in the fatal case.

Group B.—The following three cases, belonging to the preeclamptic type, are given to show the comparative results in the determination of the urinary nitrogen, in connection with the possible practical significance of the presence of indicanuria.

Case V.—Age 34. III-para. First pregnancy normal. Second terminated in a miscarriage at the third month from an unknown cause. Present pregnancy uneventful, except for occasional and moderate indicanuria, until the beginning of the eighth month, when the urine showed the following: specific gravity, 1.026; albumin, 2.5 per cent.; no casts; large amount of indican. The albumin and large amount of indican persisted, and at the end of the month a few hyaline and granular casts appeared. There were no other symptoms, except some lassitude, mental depression, and flatulency. A determination of the nitrogen partition showed the ratios to be normal, so that it seemed fair to conclude that no serious disturbance was taking place beyond that of an intestinal toxemia. A milk and cereal diet was followed by a decrease in the amount of albumin and indican, and in the disappearance of the casts, although a moderate increase in the indican and a trace of albumin persisted until two weeks after the labor, when they disappeared simultaneously. The nitrogen determination, in this case at least, seemed to be of practical value in the increased assurance it afforded us of the safety of the patient.

Case VI.—Age 30. Operated upon for appendicitis three months before this, her first pregnancy began. During the second month of the pregnancy an attack of persistent vomiting finally yielded to catharsis and saline irrigations of the rectum. The urine, unfortunately, was not completely examined at this time, but the ordinary clinical test presented negative evidence. A mild recurrence of the vomiting appeared two months later, but promptly yielded to treatment. Recently, during the second month of this pregnancy, an attack of headache, dizziness, spots before the eyes, and moderate edema of the legs occurred. The urine again showed nothing by the ordinary clinical tests except a slight increase in the indican. The determination of the nitrogen partition showed that only 55 per cent. of the total nitrogen was excreted as urea; that the amino-acid nitrogen was increased to 15 per cent.; the ammonia nitrogen was 5.14 per cent. Catharsis and a rigid diet was followed by a disappearance of the symptoms. A return to the ordinary diet two weeks later was followed by headache and an attack of blindness that lasted one day. A second urinary examination, made a few days subsequent to this reappearance of these symptoms, showed the following: specific gravity, 1.011; no albumin or casts; a slight increase of indican; the presence of leucin. The ratios of the nitrogen were: urea, 64.19 per cent.; amino-acids, 17.05 per cent.; ammonia nitrogen, 6.19 per cent. Compared with the first examination, we find the percentage of urea to be slightly higher, but the amino-acid nitrogen has also slightly increased, and leucin, that was absent at the first examination, is now present.

Case VII.—Age 39. I-para. Pregnancy had been normal, except for the transient appearance of a trace of albumin in the beginning of the seventh month, a persistent low specific gravity, and a moderate indicanuria. An excessive amount of liquor amnii was noted in the seventh month. During the latter part of the eighth month a marked edema of the legs and hands, and considerable shortness of breath appeared. There was also a moderate urticaria. The ordinary clinical tests of the urine at this time again furnished practically negative evidence, with the exception of a trace of albumin and a low specific gravity. A determination of the nitrogen partition showed the urea nitrogen to be 73.14 per cent.; the amino-acid nitrogen 15.9 per cent.; the ammonia nitrogen 6.18 per cent. Leucin was also found. Before the urinary examination was completed premature labor began, and a six-pound child was born spontaneously. A moderate jaundice began on the third day. The child died, markedly jaundiced, on the twelfth day. A second urinary examination, made at the end of the first week of the puerperium, showed the following: urea nitrogen by the Folin method, 82.5 per cent., by the Pfaundler method, 76.9 per cent.; amino-acid nitrogen, 8.4 per cent.; ammonia nitrogen, 2.9 per cent. Leucin has disappeared. Convalescence has been slow.

A comparative review of the clinical symptoms in these two groups seems to the writer to be of some importance because of the appearance of preeclamptic symptoms in Case V subsequent to a typical attack of pernicious vomiting in the early months. Williams, in a paper on "The Pernicious Vomiting of Pregnancy," read before the American Gynecological Society, May, 1905, stated that eclampsia and the vomiting of pregnancy are due to different toxins, and are clinically and pathologically distinct. The present state of our knowledge does not warrant a positive conclusion at the present time, but the clinical and chemical evidence of Cases IV and VI offer strong evidence that they are fundamentally identical, not to mention the identity of the visceral lesions in many cases.

The ordinary clinical tests of the urines in Group B present the same lack of evidence as do those in Group A. The presence of indicanuria, either mild or severe, has been noted in all of the writer's recent

cases. Although its presence is probably chiefly indicative of proteid decomposition in the intestines, and such a condition is not generally regarded as the essential factor in the etiology of the toxemia of pregnancy, yet its frequent appearance in the urine of these cases may be of some practical value in furnishing us with an additional indication that abnormal conditions exist. Case V, in which its constant presence with a small amount of albumin, furnished practically the only evidence of an arbnormal condition until the determination of the nitrogen partition was made, offers us the best demonstration of the significance of its presence. The determination of the urinary nitrogens, as in Group A, has furnished us with the most important evidence, giving us in Case V an assurance of the absence of serious disturbances, and in the other instances satisfactorily demonstrating, in the absence of other signs, that serious conditions were present. These determinations, however, have not shown that an increase in the ammonia nitrogen of either group may be considered as an index of the severity of the process, as given by Williams in his recent paper. It was increased in none of the writer's cases, excepting Case III of Group A.

The theory of acid intoxication, as applied to the toxemia of pregnancy, is imperfectly understood, and the presence of diacetic acid and B-oxybutyric, although important and probably indicative of a serious condition, does not represent the fundamental factor.

The writer's present conclusions are:

1. Inasmuch as I have so far not seen a case of pernicious vomiting of pregnancy which I considered had a hysterical or reflex origin, I have never dared to treat a case on such theories.

2. The mental symptoms of Case II were those ordinarily stamped as hysterical, but which are essentially symptomatic of the disturbed hepatic function, shown to be present by the urinary changes.

3. While the majority of cases of pernicious vomiting of pregnancy present lesions that are different from those of eclampsia, yet I have clinical and pathological evidence that they are closely related.

4. Symptoms of either group present themselves practically without urinary changes, as determined by the ordinary clinical tests.

5. The persistent presence at any period of pregnancy of even a trace of albumin, especially if accompanied by casts, and a persistent increase of indican demand a more complete examination of the urine, which seems to be best accomplished by a determination of the total nitrogen and its partition.

6. I would recommend that the test for indican be included in the ordinary clinical tests, because it seems that whatever the basic cause of the toxemia may be, errors of diet and intestinal intoxication are one of the important contributing factors.

7. Our recent study may not have added much to the treatment of the severe cases, but the early recognition of clinical symptoms and better appreciation of the disturbances in metabolism have already, I believe, been of the greatest practical value in the prevention, in some instances, of serious consequences.

41 West Seventy-first Street.

## HENRY G. DAVIS, M.D.
## A REVIEW OF SOME OF HIS WORK.

By JOHN JOSEPH NUTT, M.D.,
NEW YORK.

ASSISTANT ATTENDING SURGEON, NEW YORK STATE HOSPITAL FOR CRIPPLED AND DEFORMED CHILDREN; CLINICAL INSTRUCTOR IN ORTHOPEDIC SURGERY, CORNELL UNIVERSITY MEDICAL COLLEGE.

The pilot does not always steer his ship by watching the magnetic needle or by looking forward at a lighthouse or a star, but frequently he directs his course by taking his bearings from some object directly astern. The gold-hunter sometimes meets with the greatest success in country which has been picked and panned by numbers before him. Even in this age of the greatest advancement in all branches of medicine and surgery, may we not, with advantage, devote more time than we do, to a closer study of the ground apparently so well covered by our predecessors? May we not, perhaps, steer a better course forward and onward if we now and then correct our bearings by a glance into the past?

How frequently are new discoveries valuable, not so much by effecting radical changes, as by making new use of an old principle, or by successfully overcoming some obstacle previously insurmountable. Who can say that some methods of treatment, which have been discarded as worthless, may not be turned into the greatest value by some of us in the future? Because a man's lifework does not seem to us to bear any important relation to our present knowledge, who is competent to advise its relegation to oblivion?

In recalling to your attention the first orthopedic surgeon in this country, Dr. Henry G. Davis, it is with the hope that this review may be of assistance to some of you—may possibly suggest a solution of some difficulty in your work.

The temptation is great to seize golden nuggets from the works of others, and to ignore the heaps of gravel and sand which their industry produced. Where no nuggets are found, these heaps remain as the sole monuments to their lives, and, neglected and ignored, the winds of time are not long in effacing them. In these heaps of refuse, discarded by the diligent worker as waste matter, there sometimes may be found by-products of greater assistance to the profession than could have ever been the nugget for which the toiler sought.

Although the father of orthopedic surgery in the United States, few outside of those who make this branch their special study, know aught of the endeavors of Dr. Davis. Little mention is made of him in our present-day textbooks. Foreign writers seem to be more aware of his true greatness than

are his own countrymen. By inventing ingenious methods for the better application of principles discovered and taught by Dr. Davis, others have reaped the larger rewards. Undoubtedly we should honor those who have made it easier to apply these teachings, but let us not forget the great teacher, the originator of the basic principles. Perhaps, too, we may be able to find some truths, which, discarded as impracticable many years ago, are, by modern methods, capable of being put to the most happy uses.

In regard to the danger of our falling into imitative habits and neglecting to see new paths or the advantages to be had in reopening vacated ones, Dr. Davis wrote: "We can frankly say that for years after the truth began to dawn upon us, we were more disposed to doubt and disbelieve the evidence than to suppose that the profession had so long failed to discover what apparently was so evident. We fear this same state of mind has too often led those comparatively young in the profession to discard glimpses of light, because if true it appeared too plain not to have been before recognized by the great body of eminent men who preceded him."

The most important publication of Dr. Davis is his "Conservative Surgery" (D. Appleton & Company, 1867). In the introduction, the author gives us an idea of how important he believed his investigations to be, and yet how fully he realized that better means of obtaining the end were yet to be discovered. "The records we here present to the profession are the gradual accumulations of over thirty years' investigation. It may be thought that the amount is meager in comparison to the time spent; but it must be remembered, in extenuation, that we are but pioneers in this boundless field, and that each new discovery, effecting as it does in many instances, an entire revolution in the pathology and treatment of the difficulty, must necessarily require a long time to test, by experience, its truth. . . . The endeavor has been to discover and elucidate principles; hence, any success attained possesses a value in proportion as the subjects embraced by a principle are of advantage to man in promoting his happiness, or in prolonging his life. Principles in surgery may cover a large class of cases, whereas, manipulations or an operation may be applicable to a given case only. It is not probable that in every instance the best means has been devised for accomplishing the object desired; for we are like a traveler, crossing for the first time a vast, unexplored region, although it may be afterwards ascertained that he has not selected the best, yet it is much to demonstrate that it can be traversed by any route. We could wish for another term of life than that allotted to men, to enable us to continue these investigations; as this cannot be, we hope they will be resumed by one more capable, and pursued until the whole field has been explored."

Such expressions could come from none other than a great, a wise, and a modest man. Of conceit, he seems to have been singularly free. His demands for recognition as the originator of certain principles in practice were but the demands for justice by one who appreciated the value of his own discoveries.

The application of continued elastic extension in cases of fracture was urged by Dr. Davis, in an article published in the *American Medical Monthly* of May, 1856. Four years later, in 1860, Dr. Gurdon Buck successfully treated a fracture of the femur after this method.

The treatment of fractures by extension has now become an accepted principle, yet we know of no textbook which gives such a clear exposition of it as is given by its originator, who says: "After continued elastic extension has been applied to a fractured limb with sufficient force, and for a sufficient length of time to weary the muscles, all the tissues surrounding the fracture will be drawn tense. While in this position, and tense, they act and serve as so many splints, exerting a uniform pressure to force the parts in a simple fracture into their natural position, and, so long as they remain tense, they prevent any displacement. When the bone is comminuted, unless the fragments are isolated and detached from the tissues that adhere to them when in their place, the extension, acting upon the tissues adherent to the fragments, will tend to draw them into their relative positions with the principal bone." May not this principle be more far-reaching than has yet been appreciated?

Under treatment of fracture of the neck of the femur, Dr. Davis has a paragraph which, though published thirty-five years ago, might be quoted in every work dealing with this injury: "The great care of the surgeon should be, from the commencement, not to break up any periosteal or ligamentous union that may exist between the divided parts; for it is to this connection and at this point that we are to look for ossific union to commence. If we can secure ossific union at one point, however small, then we may reasonably look for extension of the same, and an eventual firm union." To quote further: "After partial union has taken place, the splint and apparatus for extension, which we use in morbus coxarius, can be applied, and the patient allowed to exercise on crutches."

Dr. Davis advises against manipulating, in the case of a fresh injury, to differentiate between a sprain with contusions and a fracture of the neck. In regard to this, he writes: "This precaution, as before intimated, gives to the patient the best chance of a favorable termination, which, in cases of fracture, is union by ossification, and in case there should turn out to be only sprain or contusion, the same plan of treatment is the one best calculated to benefit the patient."

From another page we quote: "In addition, we feel constrained to protest a too common practice which prevails among surgeons, and one which is of the utmost importance in its bearings upon the casualty under consideration. We allude to the inordinate desire to ascertain the fullest extent of the injury to the ilio-femoral articulation, and the unwarranted efforts made, by manipulations of the injured limb, to ascertain whether there is fracture or not, and, if so, its particular character, direction, and extent." . . . "We have a very strong corroborative evidence of there being some point of ligamentous union of the two portions of bone, that at first effectually prevents displacement, in the fact that, in so large a number of cases, there is at first *no shortening*, and many times the shortening takes place in the hands of the surgeon, after active manipulations of the limb to discover crepitus."

Under the subject of dislocations we find a most startling statement: "At the present time, by means of the principle we have promulgated, that a ligament or other soft tissue can be elongated to any desirable extent by the use of *continued elastic extension*, we have it within our power to reduce almost any dislocation, without reference to the length of time it has been luxated, and it can be done, not only without pain or suffering, but without the slightest danger to life, and with almost a certainty of a perfect restoration of the joint to all its functions." He further adds: "This is not a process by which one joint only can be reduced, but a *principle* equally applicable to all; a mode of preparing the parts by

which we can not only reduce a luxation successfully, but can do it *without violence*." And again: "By this plan of elongating the tissues, all dislocations, whether recent or of many years' standing; all fractures; all deformities that are dependent upon the soft tissues, are entirely within our control. These soft tissues can be elongated or shortened as we please. Ligaments that are inextensible, that are designedly made unyielding, are no exception to this rule. The future alone, as the principle is applied to the various misfortunes of our race, can fully develop and make evident the importance of this discovery. We have reduced dislocated hips at all periods of time from the recent up to that of fourteen years' standing, and, in the latter case, restored a clubfoot in the same limb at the same time."

The first attempts at the reduction of congenital dislocation of the hip by means of continued extension were those of MM. Duval and Lafond. MM. Humbert and Jacquier were probably the first who achieved success with this method. It remained, however, for M. Pravaz, in 1838, to prove the curability, under favorable circumstances, of congenital luxation of the femur upon the ilium. John Murray Carnochan, M.D., in his "Treatise on the Etiology, Pathology, and Treatment of Congenital Dislocations of the Head of the Femur," published in 1850, has given a clear exposition of the treatment as practised up to that time. These pioneers in the treatment of hip-dislocation, however, applied their weights in an empirical manner. They divided the treatment into three stages: The stage of preparatory extension, the stage of reduction, and the stage of normal consolidation of the articular structures, so that the head of the femur will be retained in the acetabulum.

On the other hand, Dr. Davis puts a general principle to a specific use. Extension had been used solely to make reduction possible without dividing retracted muscles and tendons. Dr. Davis applied extension with the purpose of elongating contracted tissue, and at the same time shortening elongated tissue. Thus, when the head finally reaches the socket, the muscles and ligaments about the joint are exerting equal and balancing influences upon the articulation. He says: "If the joint is equally supported, or drawn up equally on all sides, what except violence will displace it? It is at rest, neither drawn to one side nor the other. Therefore, there is no force operating to remove it from the cavity." Extension had hitherto been applied only until such time as force could obtain the reduction.

A number of surgeons since Dr. Davis' time have used this treatment, and the fact that they have had so few successes has been discouraging. Yet without assuming to be prophetic, we believe that perfected apparatus will make this the treatment by election in early and simple cases. Where an open operation is necessary to remove obstruction to reduction or to prepare the acetabulum for the reception of the femoral head, the procedure will be continued elastic extension assisted by arthrotomy. It would seem to be a more scientific procedure than the method, for instance, advocated by Lorenz. Not but that in our present state of ignorance the Lorenz operation, so called, is valuable and a blessing to humanity, and should redound much to the honor of the Viennese; yet a method in which unseen, and therefore unknown, and severe injuries are inflicted; in which hemorrhage is only stayed by the pressure of surrounding parts; in which muscles are torn and lacerated, and not incised with comparatively little injury to the fibers; in which nerves may be ruthlessly injured—such a method seems to furnish neither the scientific exactness of an open operation nor the freedom from danger of true, conservative surgery. The principle of Dr. Davis' method is at least deserving of the close study of every surgeon. To some one there may come the happiness of making it the successful means of relieving these congenital deformities.

In reference to the imperfect acetabulum frequently found in these cases, Dr. Davis says: "We would remark in this connection that, judging from the efforts of Nature to retain the functions of the joint, although the several parts comprising it are in new and abnormal position, we are encouraged to believe that, when the imperfect (by reason of arrest of development) head and neck of the femur are placed in what may exist of an acetabulum and retained there *unremittingly*, the functions of the joint being kept up and stimulated by passive exercise of the parts, that, after we have done this much, the original law of development will come to our aid, and that sound parts will be partially, if not wholly, restored, or at least will keep pace with the future growth of the body." . . . "There have been instances where all the parts of a joint, even to bone, have been formed where none existed previously."

Dr. Davis was the first to recognize and point out the factor in causing destruction in diseased joints, of the interarticular pressure produced by contraction of the muscles passing over the joint. In the chapter on synovitis, on page 206, he says: "We consider it fully established, that when disease about a joint renders the movements of that joint painful, that the joint is always liable to be destroyed by uninterrupted pressure effected through the contraction of the muscles passing over it. They do this by preventing the parts pressed upon from receiving nourishment, in the same way that a bedsore is produced." Until he brought this view to the notice of the profession, in a paper read before the New York Academy of Medicine, in 1860, it was the belief that destruction of the joint following a synovitis was always due to an extension of the primary inflammation.

Many surgeons use immobilization with little or no idea of any of the physiological action it tends to promote. "It produces rest of the part, and thus assists nature in healing," is the extent of their knowledge. If the part does not heal under treatment by immobilization, they are as likely as not to try passive or even active movements "to encourage nature to exert herself." In some of their cases these surgeons may find that whatever traction was used in applying the plaster of Paris, and was retained by the splint, deserves the credit for their cures, and the absence of any traction may be the reason for the ineffectiveness of immobilization in their less fortunate cases. "The treatment of simple synovitis," says Dr. Davis, on page 209, "in its earliest stages, by extension, is as imperatively demanded as at any later period, and relieves the pain as effectually. It has been stated by some professors in our colleges, and by others, that this mode of extension was of no advantage before shortening had taken place. We wish to correct this error, and to state most emphatically that continued elastic extension is applicable not only to synovitis, but to all other diseases within the capsule; and not only there, but when parts about or in the vicinity of a joint are so painful as to compel the individual to hold the joint motionless, extension should be applied, for the reason that the pressure exerted by the muscles in holding the joint motionless will strangle the nutrient vessels of the parts held in contact."

It is in the treatment of tuberculous disease of the hip that this surgeon made his influence more

especially felt. As long as the art of surgery is studied and practised, so long will the name of Dr. Davis remain the most illustrious in the treatment of hip disease. His recognition of the damage to the joint structures, as well as the pain, which results from the impingement of the joint surfaces upon each other, is sufficient evidence of a great genius. Many writers have given much of their time, and taken much of ours, in discussing the questions of friction, and of motion, and of extension in the axis of the neck. These questions are worthy of the attention of all, but they should not overshadow the effect of continued elastic extension as taught by Dr. Davis. Some have erred in thinking that Dr. Davis' object was distraction of the joint. Others have failed to recognize the comparative importance of traction and immobilization.

Like many new methods, that of Dr. Davis was seized upon eagerly and was widely used. Such renowned surgeons as Sayre, Taylor, and Bauer became its advocates. Sayre went to England and the Continent, where he introduced the method to the profession. Then, again, like many new methods, it became the center of a great storm. Everything was discussed, often most bitterly, but usually the essence of Dr. Davis' principle was ignored because not recognized.

In the treatment of hip disease, this surgeon soon became dissatisfied with the weight, cord, and pulley. On page 213, he writes: "It soon became evident that, if this principle of continued elastic extension could be so applied as to allow the patient to walk and ride, and take outdoor exercise, we should not only add to his comfort and happiness, but it would aid in invigorating the system, thereby enabling it not only to resist the disease, but to repair the injury which might already have been inflicted." His original ambulatory splint was a wooden affair. After a year or two, he substituted one of steel. This has been improved upon in various details by other surgeons, but the principle of an extension apparatus, permitting outdoor exercise, which is the keynote in the treatment of hip-joint disease to-day, is the one discovered by Dr. Davis, and by him first shown to be practicable.

The genius of this man is well illustrated in his discovery that the extension must be applied in the direction of the shaft, or, as stated by Sayre, "in the line of the deformity." On page 221, in the last paragraph, he says: "The extension must be made in the direction which will overcome the resistance of the contracted muscles, and serve, at the same time, to separate the diseased surfaces within the joint." On this page and the preceding one he clearly and graphically explains the mechanical necessity of this extension being in the direction of the shaft, which he illustrates with a diagram. Many of the failures to obtain the expected results from the extension were undoubtedly due to ignorance of this law, and renowned surgeons performed tenotomy so as to straighten the limb. Where wisdom does not teach, ignorance is excusable, but once the light of knowledge has been thrown upon a subject, there is no excuse for ignorance. Before the time of Dr. Davis the application of a traction brace without any regard for this law was pardonable, but for surgeons to ignore it to-day is inexcusable. Many useless joints and many avoidable operations result yearly from a disregard of this law in the application of traction.

It seems to us that the introduction of chloroform and ether interfered with the study of mechanical physiology and of Nature's more minute expressions of health and disease. Almost the first thought of the general surgeon, where an arthritic trouble exists, is to anesthetize. Thus all of Nature's indicators are lost, and only gross pathological conditions are discovered. As an assistance in certain instances, a general anesthetic is frequently confirmatory and sometimes necessary, but had the orthopedic surgeon to do without either the evidence from nature or the evidence from the condition when nature is in abeyance, he would, without hesitation, discard the anesthetic as an assistant in making his diagnosis. This principle of the direction in which to apply the traction force in joint disease, as discovered by Dr. Davis, and taught by him, must necessarily be ignored by those who apply their apparatus with the patient anesthetized.

The application of the adhesive strips to the thigh and leg for traction are according to the general plan as taught by Dr. Davis. Few know, or stop to think, that the profession is largely indebted to him for this method, without which constriction of the part and a long line of complications would be unavoidable. In truth, the spiral bands make the continued application of traction possible.

Dr. Davis was a physician in the broadest sense. In treating a part, he did not neglect the whole. He emphasized the necessity of caring for the general health. In treating a diseased joint, for instance, he advised as little restraint as possible to the normal actions of the body. The constitutional treatment is not more wisely taught to-day than it was a generation ago by Dr. Davis. For instance, how rich in wisdom are such sentences as: "Stimulants in chronic diseases never do any good any further than they promote digestion and assimilation of food. Our dependence must be upon nutritious food efficiently digested and assimilated. Meals should be served regularly and punctually. If the patient is in the habit of having his dinner at 1 P.M., which is the proper time, he should not be kept waiting; for the stomach, from habits of punctuality, acquires the habit of secreting the gastric juice in anticipation, as it were, of the coming meal, and if it is delayed the gastric juice is apt to irritate the stomach and pass into the duodenum. It will be remembered that patients with this disease (morbus coxarius) are to be put in the highest possible state of vitality; therefore, not even the most trivial thing should be allowed to interfere. If the patient is a child, it is well to give him an associate during meals, and let both be under the care of a cheerful nurse who devotes her time during the meal to cheerful, amusing conversation. Avoid, if possible, for the patient, a dark room. Sunlight is one of the requisites of health, besides the mere fact that it renders the room pleasant. It is not well to inform patients that they are to eat; for the same reason, it is not well to make eating a subject of conversation."

His directions as to the local treatment in joint disease would be creditable to a surgeon of the twentieth century. Some writers and lecturers are teaching, as original, methods devised by Dr. Davis. One of these is the scheme of cutting a hole the size of a nickel in a piece of adhesive plaster and applying it to the part. The hole is then filled with an ointment, which is thus secured from spreading. This is described on page 222 of his Conservative Surgery.

In speaking of the opening of a joint abscess, he says: "We avoid thrusting the finger into the opening for the purpose, as some surgeons do, of exploring. Surgeons seem to forget that the finger acts injuriously, as would any other foreign body, and that the flesh of a person reduced by hip disease is in that low state of vitality that it is readily induced to take on a low grade of inflammation, and

thus yield what little vitality it has. We speak from observation, and in every case where the abscess was simply opened, injected with water, using but a slight pressure to remove the matter or the water, and then injecting the chloride of soda, the abscess has closed up without any constitutional disturbance."

Many surgeons to-day would have better success in their treatment of abscesses if they followed the directions of Dr. Davis to the letter, rather than continued their rough methods, even fortified as they are with phenol and bichloride of mercury.

The Seminole, Sixty-ninth Street and Broadway.

## A METHOD FOR THE STERILIZATION OF SEA-TANGLE TENTS.

By O. L. MULOT, M.D.,
Brooklyn, N. Y.

Only a limited experience is necessary to convince one that the class of cases in which cervical dilatation is indicated is a large one. At present the rapid method, by divulsers of one or other variety devised for that purpose, is most generally practised; nevertheless there are good authorities who argue for the slow, gradual method, *i. e.*, by tents—sea-tangle, tupelo, or sponge; and even many of the devotees of rapid dilatation admit the soundness of the arguments and the advantages of slow dilatation, but urge that tents cannot be sterilized. Placing them in sterilized rubber fingercots has been advocated and practised, but this in no small measure increases the difficulty of insertion, particularly in a cervical canal of small caliber. Then, too, there is danger of pushing the tent through the rubber covering, and also there is no means of correctly gauging the amount of water that should be enclosed with the tent to insure its greatest swelling. This method, while theoretically good, presents too many difficulties and uncertainties ever to bring it into general use and favor.

The writer, having a case in which dilatation seemed imperatively indicated, and there existing contraindications to general anesthesia, decided upon tents. Procuring some sea-tangle tents, I soaked them for seventy-two hours in tincture of iodine (U. S. P.), and after that immersed them in 95 per cent. alcohol, to remove the surplus iodine. This proceeding does not destroy the swelling capacity, as one can easily prove for oneself. How deeply the iodine penetrates the tent can be seen by soaking one in water after removal from the tincture and before placing it in the 95 per cent. alcohol. Split it with a knife after it has swelled, and the iodine stain band can be seen. Tents thus treated I have left *in situ* for thirty-six hours without the slightest sign of mischief; no rigors, no fever, and an occasional one-fourth of a grain of morphine controlled the pain. Such dilatation seemed more lasting than that of the rapid method. I certainly believe my patient was more comfortable than had she been subjected to general anesthesia, with its objectionable sequelæ.

Another method of sterilization has suggested itself to me. Sea-tangle tents can be boiled. This will cause them to swell to their fullest extent. Then they should be exposed in sterile receptacles (test tubes will do); suspend from cotton plugs in an oven or hot air chamber, and in a few days they will shrink to their original size.

Either of these methods, or possibly combining the two, first boiling and shrinking, then soaking in tincture of iodine, will, I think, make sea-tangle tents aseptic and safe to use, provided, of course, there is no slip in the technique of insertion.

In stenosis of either the external or internal os, flexions and their concomitant dysmenorrheas, and endometritis due to the obstruction to the free flow and the possible retention of some of the menstrual discharge, I think dilatation by tents would be available and materially simplify the treatment.

1186 Halsey Street.

---

**The Mechanism of the Pain in Migraine.**—Francis Hare advocates the view that the pain of migraine is the true analogue of the dyspnea of asthma, in that it is caused by a peculiar pathological modification of vasomotor action, and depends proximately on vascular distention at the seat of pain, due to a vasodilatation which is compensatory of, and exaggerated by, widespread peripheral vasoconstriction. In most cases the patient is very chilly; while the body is cold the head is hot. Probably in the majority of patients the pulse rate is unaffected, for in this affection the vasoconstriction and vasodilatation may be accurately balanced; this, however, may not be always true. It is known that anything which reduces the vascular distention will relieve the pain, and *vice versa*. The writer has made a series of observations on the effects of compressing arteries during migraine paroxysms; for example, in unilateral migraine, pressure on the common carotid of the same side completely removes all pain at once, while pressure on this artery on the opposite side increases the pain. In bilateral migraine, pressure on either common carotid removes the pain from the corresponding side and increases the pain on the opposite side. General vasodilatation or that in the peripheral constricted area generally affords immediate relief; a hot bath has this effect; dry cupping is useful, and sipping of hot liquid may relieve the pain. The nitrites dilate the periphery. Exercise during paroxysms at first increases the pain, but, steadily persisted in, it shortens the period of migraine. Reduction in the force or frequency of the heart-beat may afford much relief; hemorrhage of any kind gives immediate relief. The writer declares that the evidence that the pain of migraine is due to vasomotor action seems sufficient.—*Medical Press and Circular.*

**Operative Treatment of Gunshot Aneurysm.**—T. Kikuchi writes an interesting account of his experience in operating on bullet wound aneurysms. He describes the following method as being the most convenient one, adding that it must be limited to cases in which the circulation of the afferent vessel can temporarily be stopped by means of a tourniquet tube or by the pressure of the fingers. With the tumor of an artery or vein one of the extremities, a tourniquet should first be applied and the skin and muscle be successively cut wide open. If muscle be found covering the tumor, it should be freed and pulled apart to one or both sides. When the tumor is reached it should be incised vertically with as wide an opening as possible. The coagulated blood is removed and the inside is wiped clean. Care should be taken in the search for the bullet wound. In a doubtful case a bougie should be used for exploration. The injured vessel is then freed and tied close to the hole, the part containing the hole being excised. After the tourniquet is removed, a piece of iodoform gauze is inserted. The muscle and skin are sutured in two layers. The writer states that if the common method of operation upon an aneurysm is designated as the tying of the injured vessels at their juncture on the outside of the sac membrane, his method must be styled the tying of the injured part of the injured vessels on the inner side of the sac membrane. The writer points out several advantages of his method. It makes the operation easy; the time for operation is greatly shortened; the loss of ramifying branches is reduced; in some cases operation can be performed under mere local anesthesia; the part of the injured vessels that is excised is very small, obstruction of circulation is much diminished, and the danger of consequent necrosis is small.—*The Sei-i-kwai Medical Journal.*

New York, August 19, 1905.

## THE INFLUENCE OF CHEMICAL CONSTITUTION ON THE CHARACTER AND THERAPEUTIC APPLICATION OF MEDICINAL AGENTS.

THAT constitution alone determines the physiological and therapeutic action of chemicals becomes more and more in evidence as we more clearly understand their atomic groupings, molecular configuration, and physiological effects. This law is not only of great interest and value to the chemist, but of vital importance to the therapeutist, for the combining of medicinal products with constituents of the gastric, intestinal, and tissue fluids and contents as well as of the secretions of the various glands, influences the success of treatment. Therefore, a knowledge of chemistry, physiological and otherwise, would seem to be requisite to the intelligent practice of medicine. The selective action of the cells for certain chemicals and the resulting compounds determine the benefit of treatment, as often altogether different products are formed in the animal economy than are sought for, the new compounds having sometimes an action very far from desirable.

When we realize the numberless chemical products that are formed by the various groupings of the atoms of carbon, hydrogen, oxygen, and nitrogen, and that it is not the symbolic but the structural formula which determines the characteristics of the molecular configuration, we are amazed. A specific or identical number of atoms of these various elements will in one grouping produce an acid, in others an alkaline or neutral substance. Take for illustration $CH_4N_2O$; in one instance we have ammonium cyanate, a highly poisonous substance, while with another grouping we have urea, a product of metabolism found in all animal organisms and lately highly recommended for the treatment of tuberculosis. Why these distinctive differences we cannot understand. All that we know is that these various resultant products are acid, alkaline, or neutral because of the configuration.

Then the changes of substances within the organism resulting from contact with the secretions; the saliva, which is but slightly modifying; the stomach contents, especially HCl (pepsin exerting scarcely any action on drugs); the intestines, in which many drugs undergo important alterations through contact with the intestinal juices, including the bile and pancreatic juice. These juices dissolve insoluble acids and saponify many drugs, making them susceptible of absorption and thus active. Through their alkalinity the intestinal juices precipitate many substances from solution, thus withdrawing them from absorption and allowing of a local action in the intestines.

The syntheses which take place in the organism often hamper and entirely abolish the action of drugs. Thus, benzol when given, is changed to phenol, and this in part oxidized into dioxybenzol; propylbenzol is oxidized into benzoic acid; salicylic aldehyde is oxidized into salicylic acid; toluol and cinnamic acid to benzoic acid; chrysarobin goes over as chrysophanic acid. Many of the ortho-combinations are readily oxidized in the organism while the meta- and para- series offer much more resistance. In addition to these processes of oxidation, a series of syntheses occur in the organism, the chief use of which is to render toxic substances harmless. These syntheses bring about mated combinations of residues of the alcohols and phenols, which combinations are physiologically inert and are eliminated as soluble salts in the urine. In this mating, the sulphuric acid which arises from the oxidation of sulphur in the albumin plays an important part, and indifferent ether sulphuric acid is formed by it from the most poisonous substance. Substances which pair are always poisonous, while non-poisonous substances seldom pair.

Differences exist in the toxicity of ortho-, meta-, and para- compounds, the latter as a rule being most poisonous. Some compounds show the reverse behavior. The para- and meta- oxybenzoic acids are both inactive, while the ortho- compound (salicylic acid) exerts a well-known energetic action. Pyrocatechin, the ortho- combination of the dihydroxybenzole is quite poisonous, while the para- compound (hydrochinon) is less so, and resorcin, the meta-combination, the least. Other differences exist; the ortho- and meta- compounds irritate the vagus, while the para-combinations weaken its action. Then these combinations have still more striking differences; ortho-benzosulphinide, which is known as saccharin, for example, being five hundred times as sweet as cane sugar, while the para- compound is tasteless.

Ferrous salts do not affect the pulmonary capillaries, while ferric salts cause their contraction. The former arrest the activity of the heart, while the latter increase and strengthen it. The action of the ferric salts upon the nerve centers is very definite, while the ferrous salts are almost without effect. The ferrous salts delay or prevent the coagulation of the blood, while the ferric salts favor it. Finally, the ferric salt is much more poisonous than the ferrous salt.

The alkalies cause cardiac arrest in diastole, while the alkaline earths, on the other hand, arrest the heart in systole. Very soluble substances are absorbed much more readily, and under ordinary circumstances produce a more extensive effect than the insoluble, because a larger amount of the substance affects the cell in a unit of time. Solubility and volatility at ordinary temperature greatly influence the action of substances. Thus the volatile hydrocarbons of the petroleums show the narcotic group action of these compounds, while the fluid and insoluble members of the same group—paraffin oils and solid paraffin—are entirely inert.

Pharmacology should receive the greatest amount of study and painstaking investigation, for with a perfected knowledge of the chemical and physiological action of individual drugs only can come the intelligent and scientific treatment of disease.

## THE PURIFICATION OF WATER SUPPLY BY COPPER SALTS.

It is now some time since Dr. George T. Moore first suggested the use of copper salts in the purification of drinking water, and his method has had a very extensive and critical trial in many cities under very diverse conditions. The subject was recently discussed at great length at a meeting of the Washington Academy of Science and reported in *Science* for April 21. Dr. Moore, in opening the discussion, said that in almost all of the numerous towns of this country where a bad odor and taste have been noted in the water supply, the cause has been shown to be the growth of certain species of algæ. The Bureau of Plant Industries was led to investigate methods of preventing this growth, for though analysis shows the waters to be harmless, they are too foul for use and people are sometimes driven from them to polluted wells and springs. Copper sulphate in a dilution of 1:50,000,000 was first employed for extermination of the dense algal growths which choked the watercress in the streams of the South. It was then used as a purifier of water in reservoirs. At Winchester, Ky., the reservoir water developed an intolerably strong odor and taste, but within three or four days after the addition of copper sulphate in dilution of 1:5,000,000, the water became perfectly clear and free from odor. The success in this case led to the more extended application of the method. During the last six months of 1904 more than fifty large water supplies were successfully treated in this way. The cost of treatment may vary from ten to fifty cents per million gallons. Opposition to this use of copper is based on the wide-spread idea of its poisonous nature. But Moore insists that the evidence of its harmlessness is convincing.

Dr. Henry Kraemer, of the Philadelphia College of Pharmacy, next spoke of his work with metallic copper in water containing typhoid and colon bacilli. Neglecting technical details, his results are summarized as follows: (1) Colon and typhoid bacilli are completely destroyed by placing clean metallic copper foil in the water containing them; (2) the effects of colloidal copper and copper sulphate in the purification of drinking water are, in a quantitative sense, much like those of filtration, but the organisms are destroyed; (3) pending the copper treatment of water on a large scale, the householder may employ copper for this purpose with safety. Kraemer thinks the copper treatment may be resorted to in emergency, even if not regularly in connection with filtration.

The value of copper sulphate in destroying mosquito larvæ was discussed by Dr. C. L. Marlatt, of the Bureau of Entomology. The use of kerosene for this purpose has the disadvantage of rendering the water unpalatable. The effectiveness of the salt was found to be diminished in foul water or water containing much earthy matter, owing to its rapid precipitation. Also the strength required increased markedly with the age of the larvæ. Marlatt concludes that, as far as the mosquito problem is concerned, the value of copper sulphate seems limited to the protection of small bodies of comparatively pure water. But in tropical countries, where most of the supply is kept in cisterns, the method may have distinct usefulness, particularly, perhaps, against the yellow fever mosquito.

It is impossible to give more than an outline of the remarks of Dr. W. H. Wiley, Chief Chemist of the Bureau of Chemistry, which were intended, he said, as a caution against the use of antiseptics in themselves harmful. Among other points the following were made: The public should not be forced to consume antiseptics in foods, especially not in water, which is of universal consumption. The general opinion of experts upon the presence of copper is decidedly unfavorable. Hence *any* residual copper in the water supply is objectionable. As shown by the preceding speakers, however, copper sulphate may be used in quantities sufficient to kill algæ without leaving any excess. If, also, it could be used to kill pathogenic germs, and the residue were entirely precipitated afterwards, then the chief objection to its use as a germicide in water would be removed.

The Health Officer of the Port of New York, Dr. A. H. Doty, expressed his belief in the value of copper sulphate as a deodorant and clarifier of water, and described the prompt disappearance of the fishy odor and taste from a reservoir in western New York after treatment with this reagent. He endorsed as economical, effective, and safe the use of copper in small amounts against algæ, but not its use for sterilizing reservoirs suspected of containing pathogenic organisms. A sudden, serious epidemic of typhoid fever without known cause would justify the assumption that the water supply was the medium of infection, but since generally the organism cannot be detected in the water, it would be impossible to determine when sterilization with the copper salts was accomplished. Besides, it is the primary source contributory to the reservoir which must be found and disinfected.

---

## The Health of School Children.

A very important investigation has just been completed by the health authorities of this city. The information obtained a short time ago, when an inquiry was made regarding the number of children who came breakfastless to school was so surprising that a more extensive investigation of the general health of school children than has hitherto been made was planned. Four schools of the primary grade were selected from the poorer quarters, but not from the worst sections, in order that fairly representative results might be obtained. One hundred inspectors were detailed to examine the children of these schools, and the results announced show a startling state of affairs. The exact number of children examined was 13,941, and of this number 6,294 are described as requiring medical attention. Defects of vision and swollen cervical glands were the most prevalent defects, the number affected in this way being in each case over 3,000. Bad as this showing is, it is more than paralleled by recent studies of a similar nature made in Great Britain. Two years ago a medical census of the school children of Edinburgh revealed the fact that 70 per cent. of them were actually diseased, and in London the conditions were found equally deplorable. The question is being taken up in earnest by the New York Health Department, and far-reaching plans are being made for the extension of the system of examination and for attempts at improvement of the health of the city's vast child population. The records of the examinations are entered in a card index and the parents of each child are to be notified of the abnormality noted and advised to obtain medical advice. At the end of a month the child is to be reexamined, and if it is found that the parents have not consulted

a doctor, a health inspector, or a nurse will visit the family and find out why not. This work is one of exceeding importance for the welfare of the coming generation of New Yorkers, and the Health Department should be seconded in its efforts to ameliorate the existing evils by the financial aid necessary to prosecute so extensive an undertaking.

### Venesection.

The view as to the utility and significance of bloodletting has fluctuated widely in accordance with current pathological doctrine, the procedure being at one time most highly lauded and at another time not less heartily condemned. There is scarcely a morbid state for the relief of which at some stage venesection has not been recommended and often employed. Clinical and experimental observations have shown that the withdrawal of blood is capable of inducing certain definite results, and in general it may be stated that the measure is indicated when such results cannot be more readily and more effectively obtained by other means. From an extensive study of the literature of the subject, in conjunction with clinical and experimental observation, Dr. Alexander Strubell (Der Aderlass, August Hirschwald, Berlin, 1905) has reached the conclusion that, in accordance with the amount of blood withdrawn, a reduction in vascular tension frequently occurs. This may be exceedingly slight, because (1) the caliber of the vessels readily adapts itself to their lessened content, and (2) the amount of blood lost is rapidly replaced by fluid absorbed from the tissues. In addition, relief is afforded to the left auricle and the pulmonary vessels and tissues. In order that these conditions shall be fulfilled, however, the tissues must contain a certain amount of fluid and the vessels must be capable of responding to vasomotor stimulation. In conjunction with the abstraction of blood the amount of albumin and of hemoglobin is diminished and the amount of water is increased. The specific gravity of both the blood and the serum is reduced, while there is a relative increase in the amount of salts. In addition to the direct loss of red corpuscles and of hemoglobin a certain amount of cellular degeneration takes place. Two hundred and fifty cubic centimeters is a fair average amount of blood to withdraw for ordinary therapeutic purposes. When the procedure is employed for the removal of toxic substances from the blood the effect will be greatly enhanced by the introduction of decinormal salt solution to an average amount of 400 c.c.

### Eyestrain as a Cause of Headache.

There has been considerable diversity of opinion as to the effect of eyestrain in the development of various morbid states, but there is a growing conviction that, while such strain cannot be held responsible for all the ills that have been laid at its door, it is still an important factor in the etiology of certain symptomatic conditions. Of course, it has long been known that eyestrain is a prolific cause of headache and other attendant phenomena, including nausea and perhaps vomiting. It can be conceived also that it may be the means of exciting the occurrence of a paroxysm in the case of such neuroses as migraine and epilepsy, but here it can be considered only as an accessory factory. Sydenham's chorea is an infectious disease and has, of course, no relation to eyestrain, but blepharospasm may be induced by conjunctivitis secondary to eyestrain or other cause, and various attitudes of the head and movements may be brought about by attempts to secure easy and clear vision on the part of eyes whose refraction is abnormal or whose muscular apparatus is ill balanced. An interesting confirmation of the relation between eyestrain and headache is presented by Dr. G. L. Walton (*Boston Medical and Surgical Journal*, June 22, 1905), as the result of a comparative study of the prevalence of headache in 100 healthy individuals, with preserved vision, in 42 persons partially blind or totally blind, after the habit of fixation and convergence had been established, and in 90 persons totally blind from infancy, and thus free from eyestrain. Of the first group 31 per cent. had never had headache, while 69 per cent. suffered from headache with greater or lesser frequency. Of the second group only 29 per cent., while of the third group 66 per cent. had never had headache. The frequency of recurrence of the disorder was about the same in all of the cases in which it occurred at all.

## News of the Week.

**Typhoid Fever in New York.**—Apparently New York is to suffer from an unusually severe visitation of typhoid fever this year. There have already been a very large number of cases, with an abnormally high death rate. The cases have been especially numerous in Brooklyn, owing, it is supposed, to contamination of the water supply of that borough. Because of the negligence of physicians in reporting cases, the Health Department is taking the matter up actively, and is making a house-to-house canvass for cases of the disease in the Thirtieth Ward, Brooklyn. The Health Department has given out a statement, advising against the use of unboiled well or tap water in Brooklyn, and urging care in the protection of food from flies. Boiling or pasteurizing milk is also advised, and people are warned against bathing at beaches in the vicinity of sewer outlets. The situation is not so bad, however, as a resident of New York, now temporarily in New Orleans, has been led to believe. The reports reaching him were so alarming that he sent the following telegram to his son: "Take good care of yourself and get away from New York as soon as you can. Over fifty thousand cases of typhoid fever there since January 1. Don't stop in Washington. Typhoid epidemic there. Over five times as many deaths as we have had here in the same period from yellow fever." If the young man must keep moving until he gets to a fever-free locality he will be on the run for a long time.

**Yellow Fever.**—There is an improvement in the situation at New Orleans. Since the officials of the U. S. Public Health and Marine Hospital Service have taken charge a more thorough supervision has been possible, and, as a consequence, there are fewer concealed cases. This increased at first the number of reported cases and gave the appearance of an increase in the gravity of the epidemic. Up to Wednesday of this week there had been a total of 1,080 cases known to the authorities, with 171 deaths, a mortality percentage of 15.83. It is believed that the height of the epidemic has passed, and that a total of 105 new cases, reported last Saturday, will not again be reached.

**Arsenic for Yellow Fever.**—Dr. Reginald B. Leach, a homeopathic physician of St. Paul, has gone to New Orleans to determine the prophylactic virtue of arsenic against yellow fever. He claims that a small daily dose of the drug will render one immune against the disease, and is, it is said, so convinced of this that he proposes to experiment with himself by allowing infected mosquitoes to sting him. Many years ago a physician invented a fever cot by

means of which cold affusions could be repeatedly made without disturbing the patient. He was convinced that this treatment would cure yellow fever, and went to New Orleans during an epidemic to demonstrate its efficiency. He died of yellow fever on his own cot.

**Dr. G. M. Berry** of the United States Public Health Marine Hospital Service, who was engaged in the work of yellow fever sanitation in New Orleans, has been taken down with the fever. He was in charge of the inspection service in the Italian district. He had had an attack of yellow fever a number of years ago, and was regarded as immune. He is, we are glad to say, now reported to be convalescent. One other physician, Dr. John T. Crebbin, has also had the fever and has recovered.

**The Idiocy of Quarantine.**—Several of the panic-stricken communities in Mississippi and Louisiana are on the verge of a famine, owing to the severity of the shotgun quarantine they maintain, excluding all manner of freight and the mails, not only that coming from New Orleans, but even from other towns as fear-ridden and closely guarded as themselves. One town in Louisiana has actually refused to admit a consignment of carbolic acid, sent to it for disinfecting purposes, and another has turned back a carload of steel rails.

**Autopsies at the Craig Colony for Epileptics.**—The last legislature gave to the authorities of the Craig Colony the right to make autopsies on the bodies of epileptics dying at the colony, who had been supported therein wholly at the State's expense. The following is the clause in which such authority is given: "The superintendent shall have power, subject to the supervision and control of the board of managers, in case of the death of any patient at such institution who shall have been maintained therein wholly at public expense, to make, or cause to be made, at the said Craig Colony by a member or members of its medical staff an autopsy on the body of such patient, provided that such autopsy be made not later than twelve hours after the death of such patient, and that it be confined exclusively to the brain and made in such a manner as will cause the least possible mutilation, and provided also that the said Craig Colony shall print conspicuously upon all application blanks used in admitting patients to the institution the fact that the officers of said colony have the above stated powers in relation to the making of autopsies." Previous to the enactment of this law, autopsies were made on 50 per cent. of the patients dying at the colony, and it is believed that under the new law autopsies will be made in fully 95 per cent.

**Medical Hall of the U. of P. Burned.**—Fire destroyed the old medical hall of the University of Pennsylvania, at Thirty-sixth Street and Woodland Avenue, Philadelphia, on Monday of this week, and threatened the main group of buildings of the institution and the great hospital across the street. The loss is $150,000.

**The Evangelical Lutheran Hospital,** at Granite City, Ill., was dedicated on August 13. The building was erected at a cost of $40,000, the funds being contributed by friends from all parts of the country. The hospital is four stories high, with dimensions of 85 by 115 feet, and will accommodate about 100 patients.

**Prize for Essay on Trachoma Awarded.**—The prize of 1,000 kronen, offered by the Hungarian Government for the best essay on the treatment of trachoma, has been won by Professor Kulmt of Königsberg. The second portion of the prize, also of 1,000 kronen, for an essay on the pathology of the disease, was not awarded.

**Typhoid Contamination Threatens the Boston Water-Supply.**—There are so many cases of typhoid fever in Worcester, Mass., as almost to justify the term epidemic. Seventeen cases were discovered in one day. The origin of the disease has been traced to a spot near Holden, in the watershed from which Boston draws its supply.

**War Against Hokey-Pokey Ice Cream.**—An investigation is to be made by the Paterson Board of Health of the ice-cream sandwiches peddled from street stands. If it is found they contain a dangerous proportion of bacteria or other impurities the hawking of the stuff in the streets will be prohibited.

**Pennsylvania State Medical Examinations.**—Of 466 candidates who presented themselves before the Pennsylvania State Board of Medical Examiners on June 28 for examination to secure license to practise medicine, 320 passed, 56 failed, 4 were rejected for cheating, and 4 withdrew; decision was reserved in 82 cases.

**Dr. H. W. Hill,** who for some years has been director of the bacteriological laboratory of the Boston Board of Health, has handed in his resignation, to take effect September 1. He has accepted the positions of assistant director of the Minnesota State Board of Health laboratory and assistant professor of bacteriology of the University of Minnesota.

**Dr. Charles P. Thayer** has resigned the post of secretary and chief executive officer of the Tufts College Medical and Dental Schools, of which he was practically the founder. He will be succeeded by Dr. F. N. Briggs.

**Texas Fever** is sweeping Indian Territory, and a Government inspector says that over 5,000 cattle have died in the Chickasha Nation in two weeks. Whole herds are infected, and the loss to cattlemen will run into millions, it is feared, before the fever is stamped out.

**Missouri Tuberculosis Sanatorium.**—The commissioners appointed by Governor Folk of Missouri to choose a site for the location of the State sanatorium for the treatment of incipient tuberculosis, have completed their tour of inspection of the various proposed locations. About the 1st of September the commissioners will visit the State institution at Rutland, Mass., and similar institutions in Rhode Island and New York. Upon their return, they will choose a site for the sanatorium in Missouri. The legislature appropriated $50,000 for the erection of the building, and provided that it should be located at a point at least 1,000 feet above sea level.

**Mosquitos in London.**—Reports from London indicate that the city is suffering from an altogether unaccustomed plague of mosquitos. A few years ago they were almost unknown, or made their appearance fitfully in the neighborhood of the docks and Fleet Street, coming, it was supposed, among the rolls of paper. This summer they are being found all over the metropolis, and not a suburb is free from them. Apparently their bites are very trying to the insular skin, for it is stated that the physicians and hospitals are kept busy treating patients suffering from the effects of the punctures.

**Sea Water for Tuberculosis.**—A French physician, Dr. Quinton, who has been experimenting with sea water in the treatment of tuberculosis, has communicated his results to the Paris Academy of Medicine. The sea water is sterilized and injected hypodermically every three or four days in doses of from 50 to 300 c.c. It is used diluted with distilled water, so that its total saline strength is 0.7 per cent. So far,

Dr. Quinton has treated eighteen patients, who gained steadily in weight. Only three, in whom the disease had progressed very far, showed no improvement, while in the fifteen others a decided improvement was effected.

**Much Unsafe Milk.**—More than one hundred men are now employed in inspecting the milk sold in New York City, and over 13,000 quarts have been condemned since August 3. An especial effort is being made by the Health Department to improve the quality of the milk sold in the tenement districts.

**Another Appendicitis Theory.**—Dr. Pond of Liverpool has published in the *Lancet* a new theory concerned with the production of appendicitis and other intestinal disorders. He believes that such ailments may be the result of antimonial poisoning, and that this may take place through the rubber washers used in closing bottles with patent spring stoppers. Dr. Pond claims to have established the fact that such rings consist of almost one-third their weight of antimony. Not only is the antimony dissolved by the mineral waters containing alkalies and organic acids, but these rubber rings, as daily observation shows, soon become brittle and some of the compound falls into the contents of the bottles.

**American Electro-Therapeutic Association.**—The annual meeting of the American Electro-Therapeutic Association will take place at the New York Academy of Medicine, September 19, 20, and 21, 1905, under the presidency of Dr. Emil Heuel of New York. The secretary is Dr. Clarence Edward Skinner, 67 Grove Street, New Haven, Conn. An interesting programme is announced.

**Quacks in Prussia.**—According to the latest statistics obtained by the authorities, the number of quacks in Prussia has undergone considerable increase. The present number is given as 5,148, against 4,104 in the previous year.

**Statistics of Cremation.**—The French Society for the Encouragement of Cremation has recently held its annual meeting in Paris. The secretary reported that there are now ninety crematories in Europe and America, in which so far 125,000 bodies have been incinerated. There are nine crematories in Germany, in which during the past year 1,381 bodies were burned, a gain of 300 over the previous year. During 1904 only 354 cremations were carried out in France. This method of disposing of the dead is becoming more popular in South America, and 370 cremations are reported from Buenos Ayres during 1904.

**Milk Conditions in Illinois.**—Impure milk in towns in Illinois outside of Chicago is causing a flood of complaints in the office of the Pure Food Commission. Because of poor facilities in smaller cities, such close supervision as is possible in Chicago cannot be exercised. According to complainants, formaldehyde is being used freely by milk dealers in the country.

**Work of Visiting Nurses.**—According to the report of the Visiting Nurses' Association of Chicago, 853 patients were cared for during the last month, and 3,717 visits made; fifteen sick babies were taken care of each day at the Fresh Air Station.

**The Medical Society of the Missouri Valley** will hold its eighteenth annual meeting at Council Bluffs, Iowa, on August 24 and 25, under the presidency of Dr. S. Grover Burnett of Kansas City. The secretary is Dr. Charles Wood Fassett of St. Joseph, Mo. The programme contains the titles of about fifteen papers, promised for the meeting.

**Dr. Wilfred H. Manwaring** of Johns Hopkins Medical School, at present Fellow of the Rockefeller Institute for Medical research, and assistant in pathology in the University of Chicago, has been appointed head of the new department of pathology and bacteriology in Indiana University, with the rank of associate professor.

**An Alleged Cure for Leprosy.**—A dispatch to the Associated Press from Manila announces that a cure for leprosy is believed to have been discovered in radiotherapy. Of twenty-five cases treated, all have improved, six patients being pronounced cured. All of these cured patients have been under observation for at least six months, and repeated examinations have shown the absence of the lepra bacillus from the blood and tissues.

**Typhoid Fever in Washington.**—Typhoid fever prevails to an unusual degree in Washington, 32 new cases having been reported on August 14. Since the beginning of July 290 cases have been reported. On the same day a year ago only seven cases were reported, making a total of 193 cases from the preceding July 1. An encouraging feature of the situation is that the new filtration plant is being put into operation. Water was started through two of the filter beds, having a capacity of 3,000,000 gallons each, on August 15, and in sixty days the entire plant of twenty-nine beds will be put in operation, thus insuring a complete supply of filtered water.

**Obituary Notes.**—Dr. Seth D. Boggs of Brooklyn died suddenly on August 10, while returning home from a round of professional visits. He was born in Brooklyn in 1852, and was graduated from the Bellevue Hospital Medical School in the class of 1886.

Dr. Thomas J. Maxwell died in Keokuk, Iowa, on August 1. He was born in Athens, Ohio, in 1837, and was a graduate from the Medical Department of the University of Iowa in 1861. He served in the Medical Corps of the Union Army during the Civil War.

Dr. John C. Coats of Huntsville, Ala., died July 30, after a brief illness, at the age of fifty-three years. He was a graduate of the Medical Department of Vanderbilt University, in the class of 1878. He practised for many years in Blanche, Tenn., and removed to Huntsville only a short time ago.

Dr. William May Bramlette of Florence, Ala., died August 2, at the age of forty-three years. He was born in Giles County, Tenn., and was graduated from the Medical Department of the University of Louisville in the class of 1881.

Dr. John G. Pike of Dover, N. H., died August 1, at the age of eighty-seven years. He was born in Somersworth, N. H., and was graduated from the Bowdoin College Medical School in the class of 1847. He practised in Salmon Falls, then in Boston, and later in Dover.

Dr. Robert Edwin Jameson of Jamaica Plain, Mass., died suddenly August 4. He was born in Lynn in 1837, and was graduated from the Harvard Medical School in 1861. He served in the Medical Corps of the Union Army during the Civil War.

Mrs. E. Fleischman-Aschheim died on August 3, at her home in San Francisco, directly as a result of prolonged use of the *x*-ray. Mrs. Aschheim was not a physician, but the last years of her life have been devoted entirely to radiography, fluoroscopic examinations, and other uses of the *x*-ray, under the direction of physicians, and her work has possessed such rare excellence as to have gained for her a national reputation. It became necessary in January of this year to amputate one of Mrs. Aschheim's arms, on account of persistent dermatitis and ulceration, but although the operation was successful, it did not lead to improvement of her general condition, and she finally died, a martyr to her profession.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

MEDICAL CONGRESS—ROYAL INSTITUTE OF PUBLIC HEALTH—MEDICAL DOINGS OF THE KING AND PRINCES.

London, July 28, 1905.

This is the British medical week, and a fair number of Londoners have gone to Leicester for the meeting. Some are returning to-day, but others are staying for the closing entertainments. It seems a little unfortunate that a younger association, working on similar lines, some almost parallel, should be holding its meeting almost at the same time in London. The congress of the Royal Institute of Public Health, the opening of which I chronicled last week, continued its work until Tuesday afternoon, and was divided into sections after the usual manner. The entertainments and excursions were excellently planned, and the exhibition was well worth a visit or two.

Sunday was included in the programme—special services for the sanitarians, who mustered in such large numbers, being held in the morning in St. Paul's Cathedral, in the Roman Catholic New Cathedral, in the City Temple, and in St. Columbia; while in the evening Westminster Abbey and Southwark Cathedral were largely attended by the delegates.

At St. Paul's the Bishop of London preached, and divided the world into three classes—those who looked for physical, moral, and social salvation to human effort only, keen, earnest, self-denying, scientific, but unable to look beyond the immediate present; those who were impatient when they heard of the laws of nature, and thought that with more faith death and misery could be averted; and those who saw no inconsistency in combining both ideas. Such were Newton, Herschel, Stokes. If it was not inconsistent for great scientific men to be religious, still less was it for the most devout to be enthusiastically scientific. The bishop passed on to say the doctors and the clergy met in the slums and worked together against unsanitary areas and all things injurious to health. No men were more enthusiastic on the side of the public health. He then took four of the problems discussed in the congress to enforce his lesson, viz., infant mortality, housing, immorality, and drink. To meet these great evils men must indeed work, concluded the bishop; but the work would only be permanent and effective when behind the human worker is the God who "worketh in us both to will and to do of His own pleasure."

Infant mortality was largely discussed at this congress. The average death rate in our great towns is 17.2 per 1,000 living, while for infants under one year it is 160 per 1,000 births; in the smaller towns, 154, and in rural districts, 125. There are some large towns where the number exceeds 200. It is among the poorer classes that the greatest infant mortality occurs. Dr. George Carpenter, in a paper on the subject, attributed the shocking loss of life for the most part to improper feeding, and supported the scheme of municipal supply of milk (sterilized) to the poorer people on easy terms.

In the section on Preventive Medicine, a paper was read on Dietetics which gave rise to no little amusement. The author advocated a vegetable diet of one meal a day, after, as he put it, the example of Buddhist monks and Trappists. Diet, he held, would cure many diseases, even the infectious ones, at which laughter was general in the audience. Since he had lived thus his health was much improved. Medicine was a mere corollary to dietetics.

Sir J. Crichton Browne, who presided in this section, gently reminded the author that enthusiasm often degenerated into faddism, and that with decrease in the death rate there had been an increase in the consumption of meat. Further, a baby wanted food every two hours.

The proceedings of the British Medical Association will be furnished to you at length by your special staff of reporters, so here I need only say that I am told the meeting has been successful, and above 900 members went to Leicester for the occasion.

The King went to Chatham on Wednesday and unveiled a memorial arch erected in memory of the Royal Engineers who died in the South African war. His Majesty then opened a naval hospital which has been completed this year. It is situated on the top of Chatham Hill, 200 feet above the River Medway, and the grounds extend to more than 33 acres. There is accommodation for 600 patients and a staff of 90. It is arranged in pavilions joined by a connecting corridor nearly 1,000 feet long, from which the wards branch off. Begun in 1899, the hospital has cost £400,000.

The Duchess of Connaught on Wednesday opened a new nurses' home for the City of London Hospital for Diseases of the Chest, familiarly known in the East End as Victoria Park Hospital. The foundation stone of this hospital was laid by the late Prince Consort in 1851, and it has been a great benefit to the poor of the neighborhood. There are 164 beds. The open air treatment has received attention, and separate balconies have been added to both the male and female wards. The Duke accompanied the Duchess and made a speech. He lately accepted the office of president.

Princess Louise, Duchess of Argyll, held a reception at Charing Cross Hospital on Wednesday to mark the opening of the new improvements. On the same day His Royal Highness was present at a meeting of the Council of Queen Victoria's Jubilee Institute for Nurses, and presented Miss Peter, on her resignation of the office of general superintendent after fifteen years' service, with a check and a complimentary resolution of the Council.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

PHILIPPINE ISLANDS MEDICAL ASSOCIATION—DISCOVERY OF A SOURCE OF DYSENTERY INFECTION—A MEDICAL SCHOOL FOR MANILA—NEED OF NATIVE PHYSICIANS.

Manila, P. I., June 30, 1905.

At the recent meeting of the council of the Philippine Islands Medical Association it was decided that the next annual meeting should take place in Manila during February, 1906. It is the intention to invite a number of distinguished medical men from the United States and from foreign countries. The change in the time of meeting from March to February is very desirable, because March marks the beginning of the hot season, while February is one of the coolest months of the year.

The source from which much of the dysentery that has occurred among persons who were very careful about their food and drink has probably been located. The Board of Health, in its endeavor to locate the source from which the ever-present ameba finds its way into the alimentary tract of the people, took samples of distilled water at seventeen different places throughout the city, and had them subjected to microscopical examination. In seven of them amœbæ were found. It was at first thought that the water had become infected through the carelessness of servants, or, perhaps, had become contaminated by the ice, which is often dragged over the ground and afterwards washed with ordinary tap water, which is known to be infected, and then put into the water cooler. While that may account for some of the instances, the main cause is no doubt the contaminated condition of some of the storing tanks of the distilling plants. The tank of the distilling plant located near the Magallanes monument was one of those containing amœbæ, and from there they were distributed throughout the city by the water carts that receive their supply from that place. It was reported that the tank at the First Reserve Hospital was infected some time ago. It will therefore be seen that many persons who were drinking distilled water only were just as likely to contract dysentery as their brethren who were not so careful. Suspicion naturally first fell upon the water distributing carts, but investigation showed that they were disinfected daily with live steam, and no amœbæ could be detected after this procedure. There was much surprise expressed when it was announced that the trouble had actually been traced into the distilling plants. After the tanks were thoroughly cleansed and disinfected, it was found that the water stored in them for a short time, again showed the presence of amœbæ. The aërating coils, which are situated just above the tanks, came under suspicion. They were temporarily removed and the distilled water was permitted to flow directly into the tanks. After that the tanks remained free from infection. The question now arises as to how the aërating coils became infected. It has been suggested that the amœbæ were carried there by dust or dirt, or other extraneous matter, which may be blown about by the wind, but careful examinations of such material has failed to reveal any amœbæ. It would appear more likely that the employees, in cleansing the coils, may probably have used ordinary tap water, and so infected them. The plan which has been followed by many persons in Manila, viz., to boil the drinking water just before using it, would seem to be the only safe one. The foregoing experience again demonstrates that eternal vigilance is necessary to protect the average white man in the tropics against the introduction of amœbæ into his system.

The Committee on Public Policy and Legislation of the Philippine Islands Medical Association has been making a strenuous effort to have a medical school started in Manila. Numerous attempts have been made in this direction before, but they have always ended in failure. The Philippine Commission has appointed a committee, composed of Com-

missioners Worcester and Tavera. These latter gentlemen have been in conference with the representatives of the Medical Society, and it is hoped that an Act of Commission will soon be passed, which will place this matter upon a legal and working basis. The physicians who will be required for professors and instructors have all signified their willingness to serve without compensation. If the Government would extend the use of the facilities in the way of laboratories, buildings, apparatus, etc., which are already on hand, the school can be conducted with a very small annual outlay.

There is a great need of properly educated Filipino physicians. If they could be available now for work in the provinces for the purpose of relieving distress and suffering, it would probably do more to convert the people to American ideas, and to cause them to settle down to peaceful pursuits, than could be expected from soldiers and guns. Reports are received almost daily of persons who have died of some disease or injury that would have yielded readily to the means employed by a modern physician.

Colonel Byrne, of the Medical Department of the United States Army, arrived a few days ago, and assumed the duties of Chief Surgeon of the Philippines Division, *vice* Colonel Girard, who has returned to the United States on account of illness.

## AMBLYOPIA EX ANOPSIA.

To the Editor of the Medical Record:

Sir: In the Medical Record of July 8 I notice an address delivered before the New Jersey State Medical Society at its 139th session, by Dr. W. B. Johnson, on a condition of the eye which he calls "Amblyopia Ex Anopsia." He cites the histories of three cases which, he says, prove the fact that such a condition does exist. To this number I desire to add another case of my own. In explanation I will say that my left eye became affected with convergent strabismus when I was passing through my first dentition. I had congestion of the brain, with convulsions, and on recovery my left eye was crossed, my right eye not being affected. Since that time I have used my right eye, or, as I always term it, my good eye. I can see with my left eye, but my vision is indistinct, and I use my right eye exclusively. About twenty-four years ago I had the strabismus in the left eye corrected by operation, and one cannot tell that the strabismus ever existed, except that in the sunlight I still carry my left eye in a partial squint. My attention was first called to this condition by an article in the Medical Record for February 25, 1905, by Dr. D. B. St. John Roosa, and I have been thinking I would write concerning my own case, but have waited, knowing I would hear or see more on the subject. Since than I have noticed the condition of the eyes.

Two cases of convergent strabismus now under observation present what to me appears to be a somewhat peculiar phenomenon. The patients are both girls, aged 9 and 11 years, respectively. Their eyes became crossed at about the same age in both, and from the same cause, viz., convulsions attending congestion of the brain. Now, when one puts the finger on one eye and closes it, its fellow becomes straight and subject to complete control of its muscles, the children being able to look up, down, or to either side, but they cannot close one eye without closing both with voluntary muscles. They can use the finger to close one, and the other will stay open, all right. Is there not some way by which this condition can be corrected without operative procedure? I believe that there is, and that it can be accomplished through a simple course of exercise of the eye muscles. I advised the family of these girls what to do and how to do it. The results I will report at some future day. E. C. Hydrick, M.D.

Watson, Ark.

**The Successful Treatment of Foreign Bodies in the Digestive Tract by the Internal Administration of Cotton Wool.**—W. Blair Bell refers to several cases in which he has used cotton wool in order to carry along foreign bodies which had been swallowed. One child had swallowed a gold brooch. The writer teased up very finely a small handful of absorbent wool, part of which he administered in milk and part in jam sandwiches; some hours later he ordered a dose of castor oil. In the morning there was a copious motion, in which were found several egg-shaped lumps of cotton wool, in one of which the brooch was closely packed. The second patient swallowed a small brass bedknob. A skiagram was taken, and the knob was seen to be still in the stomach. A handful of absorbent wool was administered in a dish of bread and milk, and at night a dose of castor oil was given. The knob was passed on the next day. The writer believes that the wool may act in one of two ways—either by directly enveloping the swallowed body or by matting the feces together around it.—*Medical Press and Circular.*

# Progress of Medical Science.

*Boston Medical and Surgical Journal, August* 10, 1905.

**Three Cases Illustrating the Practical Importance of Recognizing the Post-Epileptic State.**—These cases are reported by Morton Prince. He states that though temporary paralysis and various forms of mental delirium following epileptic fits are well recognized, he does not think that the possibility that the paralytic and mental condition may simulate gross lesion of the brain is as fully realized as the practical importance of the matter demands. Post-epileptic state may easily be mistaken for cerebral hemorrhage or tumor, and may seem to call for operative interference, as happened in two of the cases reported. The diagnosis of post-epileptic paralysis was made in the first case in view of the fact that the patient was subject to fits, that she had testified that she had had the symptoms which always began a fit shortly before being found unconscious, that opening the skull showed no hemorrhage, that the hemiphlegia nearly completely disappeared on the second day to reappear after the convulsion, and finally disappeared completely and rapidly at some time within four days of the original attack, and that after disappearance of the hemiphlegia there was no persistent physical signs of increased myototic irritability. In reviewing the history of the second case the paralysis and other symptoms for which he was operated upon were really post-epileptic phenomena and would have spontaneously disappeared if operation had not be undertaken. While there was an exquisite ankle klonus on the right, there was no Babinski. The third case was one of post-epileptic delirium simulating insanity, one that could hardly be described as entirely pathological or unreasonable; she always had an intense dread of becoming insane and was now rapidly recovering her reason. She could not make those about her realize that she was not insane, and she was in terror of being sent to an asylum.

**Remarks on the Present Status of Surgical Treatment of Hepatic Cirrhosis.**—After reviewing the various theories as to the etiology of ascites, both mechanical and pathological, Charles Green Cumston writes of the various procedures that have been devised to increase the number of portal-cava anastomoses, omentopexy being one of the first. His review shows that there is one chance out of two for cure if omentopexy is undertaken. The proportion of cures would become much greater if the cases of improvement were taken into account; and the number of good results will increase so soon as operations are performed under more favorable circumstances. From all said it appears that omentopexy was looked upon with general favor by surgeons, although the results obtained are very disparaging. This could hardly be otherwise when one takes into consideration that the affections are so different and where frequently ascitis and some other hepatic lesion have alone been diagnosticated; and in the statistics published so far are to be found the atrophic and hypertrophic forms mixed together and, from the pathogenic standpoint, will be found alcoholic, toxic, malarial, and very probably tuberculous and syphilitic types. Numerous are the cases of cure of cirrhosis. Atrophic cirrhosis is susceptible of improvement. It is his intention to show that ascites attributed to atrophic cirrhosis has been cured and that perhaps fortunate outcomes obtained by medical treatment in the past are quite as numerous as surgical cures which have been published of late. That omentopexy may cure portal hypertension is not at all doubtful, provided the peritoneum is healthy. Omentopexy lessens the disturbances resulting from hypertension of the portal vein and may prevent ascitis to a certain extent, but indirectly so, by correcting the bad effects of venous stasis on the peritoneum, by delaying chronic peritonitis, the changes both of a toxic and circulatory nature of the peritoneal epithelium, which is the cause of ascitis. It is especially applicable when disturbances of the urinary secretion occur, and phenomena of congestion arising in the abdominal viscera, particularly of the spleen, and is also very efficacious in diarrhea and intestinal hemorrhages, hematemesis, or melena. The peritoneum should be vivacious and susceptible of giving rise to adhesions, so that a venous neoformation can be created. Even the most favorable statistics show that the mortality is high.

*New York Medical Journal, August* 12, 1905.

**A Fatal Case of Bacillus Pyocyaneus Septicemia after Surgical Operation.**—John B. Roberts reports a fatal case of general septicemia, probably from infection with *B. pyocyaneus.* The patient was a girl of nine years who was first operated upon to relieve a cicatricial deformity of the arm due to a burn. The scar tissue obliterated the axilla and tied the upper arm to the chest. There was some sloughing of the flap sutured into the axilla which was accompanied by the discharge of a greenish secretion. The wound afterwards became so healthy that it was skin grafted. Then

followed a sudden amygdalitis with lowered hemoglobin, a marked leucocytosis, and a diminished number of red cells. This seems to have been the starting point of her fatal illness. In a few weeks she apparently recovered from this acute condition and was then subjected to a second plastic operation under ether. The bronchitis which occurred afterwards might have been due to infection of the lungs from an incompletely cured amygdalitis, or a mild bronchitis might have been awakened into activity as the result of the anesthetic. About three weeks later the secretion from the sloughing wound was noticed for a second time to be greenish, and from this time until her death she suffered from some general infection. The greenish tint of the secretion, which was twice noticed, the existence before and after the time of the patient's illness of cases of blue pus in the wards, and the general symptoms exhibited by her led him to the belief that the infection was probably due to *Bacillus pyocyaneus*. Unfortunately no bacteriological examination was made.

**Adenoids.**—E. M. Sill considers adenoids from the pediatrist's standpoint. He refers to its frequency in childhood and the importance of an early diagnosis and treatment. His observations are based on 1,000 personal cases operated on. He believes that adenoid growths of the pharynx are more responsible for certain minor ailments in infancy and childhood than any other pathological condition found. A small amount of adenoid tissue in a small nasopharynx may become as formidable as a greater amount in one good sized. The diagnosis can often be made by the facial appearance, especially if the adenoids have been of long duration. The clinical picture is most striking, the open mouth, drooping eyelids, vacant, dull and listless expression, prominence of the veins at the root of the nose, contracted alae and sunken chest. When these characteristic symptoms are not present the condition may be inferred from the history of obstructed breathing through the nose, snoring, frequent colds, discharge from the nose, inability to nurse, otitis, earache and laryngismus. The treatment of his 1,000 cases was surgical entirely. Medical treatment without surgical intervention is of little avail. A description of the operation follows.

**An Unusual Sequel to Kraske's Operation.**—Charles B. Kelsey reports the following case that appeared at his office after nine years' absence: The woman was operated on for non-malignant stricture of the rectum, which he operated upon through the Kraske incision. Two years ago a tumor began to form over what remained of the sacrum and this has gradually increased in size. Examination shows a soft tumor the size of the fist, located low down over the end of the sacrum,and covered by a thick layer of skin and fat which proved to be a hernia escaping behind the rectum through an opening in the pelvis made by the old incision. Such a possible sequel to this operation has never been reported, so far as he knows, and must be exceedingly rare.

*Medical News, August 12, 1905.*

**The Treatment of Chronic Nasal Catarrhs with Sulphur.**—Louis Kolipinski says that sulphur is valuable in simple chronic rhinitis, in the hypertrophic stage; intumescent rhinitis is relieved by it, but the effects of it in atrophic rhinitis are not so good as during the earlier stages. In phlegmonous rhinitis the disease is often aborted by it. Hyperplastic nasopharyngitis is improved and scrofulous rhinitis can be much helped by sulphur. The immediate effects of the sulphur are to check the purulent irritating discharge, heal the excoriations, improve the patient's pale and languid looks and stop the sniffling, sneezing, crust formation and odor. In epistaxis from any cause this is one of the best applications, but should be reinforced for twenty four hours with the gauze tampon. Sulphur will not cure the coryza of acute nasal catarrh, but in chronic dironic diseases not requiring surgical aid and with the membrane not destroyed by atrophic degeneration, sulphur gives lasting relief from all the persistent symptoms. Sulphur may be a useful postoperative dressing, particularly in the surgery of the nasal cavities. The best galenical preparation is the official sulphur praecipitatum, U. S. P. The powder is blown into the nostrils with a strong powder blower. Applications are made two or three times a week for a month and once a week for the next two months.

**Treatment of the Individual Case in Appendicitis.**—Charles C. Allison gives sufficient data to show that there is a great difference in the mortality between the practise of the eastern and very radical wing of the surgical profession, and the analytical, conservative methods of the western surgeons. There is a difference also in their methods of treatment based upon a different conception of the pathology. The real cleavage in views seems to originate upon points as to the amount of infection the peritoneum, intelligently aided, may bear; as to the method which supports the peritoneum in this emergency, by limiting the infective process and by surrounding it with a barrier which offers at least a reasonable period of truce. The promptness with which adhesions occur is favored by rest and all admit that their development is an element of safety. Arresting the peristaltic wave from above ameliorates the inflammatory progress so essentially as to change the whole course and severity of a given attack; in other words, withdrawing food and avoiding cathartics, emptying the lower bowel by the repeated use of normal salt or standard enemata, encourages a peristalsis with a mild, gentle origin at the inflammatory zone rather than a painful, inefficient, and damaging wave which terminates there. He says it is not the interval case, nor an inflammation confined to the appendix, nor the management of a localized abscess that admits of debate, but it is especially the management of the sharp, progressive attack, most often seen during the second day with symptoms more obstrusive on the third and even the fourth days, that has led to views so divergent and, regrettably, to discussions so acrimonious. In a series of 231 cases, 71 were suppurative; of these four assumed the type known as acute, general, septic, peritonitis with one death; the only other death in this series occurred in an interval case, the patient dying from haematemesis, there being a history of a gastric ulcer three years previous.

**Malarial Hemoglobinuria.**—Lorin A. Greene relates some few personal experiences with resultant deductions. In a number of cases he has seen he is convinced that this agent which wrought such terrible destruction with the blood elements was not the plasmodium malariæ itself, but some toxin, the existence of which depended either upon the assistance or presence of plasmodium. There is a liberation in every case of remittent malaria; in the milder infections, or those of short duration, the free hemoglobin is converted by the relatively healthy liver into bilirubin. But in cases of long duration or greater intensity the congested condition of the liver prevents that organ from performing its function, and the free elimination of the hemoglobin by the kidneys follows. In his experience the use of quinine depends on the stage of advancement of the case when first seen. The hypodermic injection of quinine is indicated when he finds the spore forms in the blood or knows from previous examinations that they have not long disappeared. He advocates the administration of quinine in every case of estivo-autumnal malaria before the appearance of the hemoglobinuria. After a thorough cinchonization, if the hemoglobinuria continues, he sees no object in continuing its use. Calomel in large and often repeated doses he believes to be a valuable adjunct. The intravenous injection of the normal saline solution has been most useful in his hands. The hyposulphite of sodium in saturated solution has proven of doubtful efficacy in his hands.

*American Medicine, August 12, 1905.*

**Some Conditions Determining Variations in the Energy of Tumor Growths.**—Leo Loeb asserts the rate of tumor-growth is not only influenced by the species into which the tumor is transplanted, but also by variations which exist among individuals or families of the same species. Under certain conditions a state of active immunity can be experimentally produced. It can be accomplished more easily with some tumors than with others. The energy of tumor growth can be experimentally increased through successive transplantations up to a certain maximum. It is also possible to cause an experimental decrease in the energy of tumor growth. These variations are caused by a direct stimulating or depressing effect upon the tumor cells. (Contact metastases may occur, and different tumors which are morphologically similar or identical behave differently in this respect. The greatest care ought to be exercised to prevent a tumor from touching the wound during extirpation. The fact that surgeons operating on tumors do not become infected agrees with the facts found in experimental tumor inoculations.) Tumor growth is primarily due to an increased energy of growth of those cells from which the tumor takes its origin; it cannot be due to a lowered resistance of the organism in which the cells carry on their apparently unlimited growth. If a tumor cannot be successfully inoculated into other animals, it is probably not due to the fact that other animals are more resistant towards the growth of inoculated tumor cells than the animal in which the tumor growth developed originally, but to other causes still unknown.

**Infection in Transportation.**—H. M. Bracken, after a careful consideration of more than a hundred opinions received by him from State sanitarians, railway surgeons, health officers and inspectors, concludes that there is a real but unnecessary danger of infection with tuberculosis in many of the cars operated by city railroad companies, and by the Pullman Car Company. Street railway companies, as a rule, are not giving sufficient attention to car cleaning or ventilation. Railway officials, however, must be given credit, in many instances, for trying to keep their coaches in good sanitary condition. Many companies have elaborate regulations governing car cleaning and ventilation,

but unfortunately these are not always enforced. The greatest danger of infection is found in the sleeping car.

**Diseases of the Heart and Their Treatment.**—Otto Lerch (New Orleans, La.) emphasizes the fact that health and life depend largely on the equilibrium that exists between arterial and venous pressure. Cyanosis, dyspnea, edema of the feet and ankles, and a urine of high specific gravity, high color, containing a sediment, albumin, and sometimes casts, are the characteristic symptoms of a disturbance of this equilibrium. As long as compensation is perfect, no matter what the lesion may be, the patient does not suffer any inconvenience. The object, therefore, of all treatment must be to keep such a compensation or to re-establish it when lost. In cases with a completely broken compensation rest and drugs must be used. As soon as the compensation is reestablished the mechanical dietetic treatment must take the place of drugs, and if under its employment the heart again begins to fail, the prognosis is grave.

**Mercuric Chloride, Intravenously or Intramuscularly, for Epidemic Cerebrospinal Meningitis.**—Rich. Hogner has found intragluteal injections of mercuric chloride, twice a day, of great value in the treatment of epidemic cerebrospinal meningitis. He uses

| | |
|---|---|
| Mercuric chloride | 2 |
| Sodium chloride | 9 |
| Distilled water | 1000 |

One to 4 c.c. for intravenous or intramuscular injection, once or twice a day.

The maximum dose intravenously is 4 c.c. of the solution. Dr. Hogner prefers the intravenous injections and he cautions against extravenous injections on account of the bad local effects.

*Journal of the American Medical Association, August 12, 1905.*

**Exophoria.**—W. H. Roberts finds that a troublesome degree of exophoria can be corrected by systemic exercise with prisms. He begins with weak prisms, bases out, rapidly increases the strength, and has the patient's attention drawn to a point of light six meters distant. He interposes himself between the light and the patient, holding a ruler at first fourteen inches in front of the eyes and backs gradually toward the light, and when he reaches this he suddenly exposes it. If the light appears single after the transfer of the gaze to it, he has the patient look steadily at it for a few seconds, then, after closing the eyes for two or three seconds, if it still appears single on opening them, he goes through the exercise again with stronger prisms. He usually adds one or two degrees each time till 25 or 30 degrees are readily overcome. After the exercise, the patient should rest with closed eyes until somewhat recovered from the excessive convergence. He supplements the office exercises by giving the patient a pair of 8 or 10 degree prisms in a properly fitting straight frame, with or without distance correction. He has him practise with these for about ten minutes morning and evening, till the light can be fused at once, at a distance of six meters. As the muscles strengthen, once daily will suffice. It may be necessary to increase the strength of the home prisms two or three times, according to the results obtained. The treatment should be persisted in till the Maddox rod shows from ½ to 2 degrees of esophoria for distance, and the von Graefe test shows orthophoria for near. It is well to advise the patient that moderate exercises will be needed for an indefinite period after the treatment to keep the muscle power gained. He reports a number of cases illustrating his method and its results.

**Subconjunctival Salt Injections.**—S. D. Risley reports his personal experience with subconjunctival salt injections which are, he says, always innocuous and often markedly beneficial in various diseases of the eye. Illustrative cases are reported of their use and value in corneal abscess, keratitis, hemorrhage and suppuration of the retina, etc. The mode of their beneficial action, Risley thinks, is through the well-known protective influence of the serum albumin poured out into the aqueous humor. It is probable the injection of neutral saline solutions of low specific gravity dilates the clogged channels of exit and dilutes their contents, thus hastening the flow of the lymph and albuminoid substances through their normal channels, and that this fluid is replaced by a fresh supply still richer in albuminoid substances carrying a fresh nutritive supply to the tissues. Recent observations have led him to think that similar good effects can also be produced by the prolonged application of saline stupes at body temperature directly to the conjunctival sac.

**Incising and Suturing the Liver.**—J. Frank describes his method of excising a wedge-shaped portion of the liver and suturing, and its advantages over other methods, such as packing, cautery, and other methods of suture. He has experimented with it in 16 dogs. It consists in removing a wedge-shaped portion, including the diseased area, ligating the arterial bleeding with catgut sutures and, as soon as the hemorrhage is checked, bringing the flaps together, and with a long non-cutting needle making a running suture from one end to the other in the following manner: In case the excision is in a transverse direction, "one suture is carried through the liver tissue near the bottom of the trough, and then one superficially, and so on, alternating, until complete closure. It requires but very slight tension to approximate the flaps. The mode of suturing can be varied, according to the fancy of the operator. The main object is to bring the two flaps together, obliterating all dead space. The continuity of the liver surface is reestablished, appearing as if a new border had been constructed. No raw surface or ragged edge is left. If a portion of the liver is to be removed in a longitudinal direction to the viscus, the following method is then pursued: A wedge-shaped portion of the entire thickness of the liver is first cut out and the two broad surfaces left are now converted into troughs. This is accomplished by the excision of wedge-shaped pieces. The troughs thus formed have two flaps. When the operation is completed, the raw surfaces left of the original V are transformed into smooth, continuous liver tissue assuming the form of liver borders, and the V space left persisting as a notch."

**Surgical Bacteriology of the Mouth.**—A. H. Levings has studied the bacteriology in a large number of mouths of healthy individuals, as well as in persons suffering from various pathological conditions. He divides the nonpathological cases into four classes, clean mouths, ordinarily kept mouths, filthy mouths, and tobacco chewer's mouths. Bacteria were found in great abundance in the first class (20 cases), but were innocuous, with the exception of streptococci (two cases), bacillus coli (three cases), bacillus subtilis, staphylococcus and micrococcus tetragenus (eight cases). In thirty ordinarily kept mouths, bacteria were still more numerous. They were mostly, however, putrefactive germs which, growing rapidly, kill off others. The grip bacillus was found in two cases. In thirty filthy mouths, there were generally some pathological conditions present, such as decayed teeth or diseased gums. Millions of bacteria were present, and a much larger percentage were virulent. In ten cases the pneumococcus was found and the micrococcus tetragenus was present in a large number. Staphylococci occurred with the purulent cases. Putrefactive germs and gas-forming bacteria were common, accounting probably for the bad breath of these persons. Tobacco chewer's mouths were worst of all, the tobacco not restraining bacterial growth. The majority of the mouths were pathological, containing decayed teeth, ulcers, etc., showing lack of care. Experiments were made to show the effect of coughing on the dissemination of bacteria which was quite marked, even at a distance of five feet. Tests of various methods of cleansing the mouth and their effects on germs showed that scrubbing with warm soap and water and later decinormal salt solution, thoroughly for several minutes each, was about as useful as any method. Disinfectants alone, with the possible exception of hydrogen peroxide, were not reliable.

**The Oral Manifestations of Diabetes.**—H. Prinz includes diabetes mellitus as one of the diseases producing a distinct form of pyorrhea alveolaris, which, according to some physicians, is classed as a prodromal sign of the primary disease. He does not recognize any one organism as the cause of the pyorrhea, but considers that its general depressant effect on nutritions is sufficient to make way for the infection. While sugar has not been found in the saliva, the acid action that is produced is followed by an increased sensitiveness about the necks of the teeth. The circular ligament becomes swollen and relaxed, thus affording a ready gateway for the microorganisms. Pus pockets and necrosis naturally follow, and, according to Arkoevy, a distinct separation of the two upper centrals occurs. The upper arch becomes weakened in consequence, and more or less prognathism occurs. The rapid formation of soft, light-colored tartar is another diagnostic symptom. As far as local therapeutics is possible, the usual routine treatment should be followed, but little can be expected during the continuance of the primary disease.

*The Lancet, August 5, 1905.*

**The Spa Treatment of Circulatory Disorders.**—Leonard Williams says that since the introduction of what is known as the Nauheim system, the spa treatment of circulatory disorders has been in danger of becoming synonymous with effervescent baths and resistance exercises, and he, therefore, believes the time to be favorable for a brief review of the whole subject. The Nauheim treatment can be obtained elsewhere than at Nauheim. From the point of view of climate and accessibility Nauheim is by no means a place to which a cardiac patient should be lightly advised. Of the treatment which has made the place famous it may be said at once that useful as it undoubtedly is in suitable cases, the number of those cases is not large. The physiological

effect of these baths is to increase blood pressure which induces a slower and stronger cardiac systole, because the heart is stimulated to overcome the resistance. The duration of the baths is so managed that the stimulation is never allowed to approach the point of exhaustion and the effects are, therefore, maintained for a considerable time after its cause is removed. In these baths there is a cycle of results almost exactly analogous to that produced by the action of digitalis. He then refers to the limitations of the therapeutic value of these baths which were indicated by Sir William Broadbent as long ago as 1897. The near presence of dilatation, irrespective of its cause, does not constitute an indication for the employment of the Nauheim treatment, any more than it indicates the employment of digitalis. The treatment by Nauheim baths is quite unsuited to the great majority of cardiac disorders. The real truth of the whole matter may be summed up in saying that, as a rule which admits of very few exceptions, spa treatment is not suited to organic circulatory disorders where compensation is imperfect and that functional circulatory disorders, though sometimes conspicuously amenable to effervescent baths, are usually much better and much more scientifically treated by means other than those which are commonly associated with Nauheim. Nothing but harm can result from sending patients affected with aortic regurgitation away from their surroundings, and no spa provides sufficient excuse for subjecting a case of mitral stenosis with broken compensation to the fatigue of a long journey. In deciding upon the respective claims of the numerous spas at which cardiovascular diseases may be treated, various factors must be taken into consideration, but one general principle is that any spa at which gout is properly treated is, potentially, a spa suitable to cardiopath.

**On the Behavior of Leucocytes in Malignant Growths.**—J. B. Farmer gives an account of observations relating to the peculiar behavior of leucocytes in very early examples of carcinoma in various parts of the human body, referring more especially to a small primary renal tumor, an early case of chimney-sweep's cancer, and an early epithelioma of the penis. In all it is suggested that they were dealing with cytological phenomena peculiar to the earliest phases of the transmutation of normal tissue cells into cancerous elements

**A Case of Blackwater Fever.**—Edward S. Crispin reports this case and says the symptoms of hemoglobinuria, icterus, biliary vomiting, and acute anemia occurring during an attack of malarial fever are typical and yet at the post-mortem only a trace of malarial pigment in the liver or spleen could be found, the condition of the former being somewhat like that of a case of acute yellow atrophy of the liver. This naturally brought up the question of the real connection between hemoglobinuria and malarial fever and the administration of quinine. A patient from a malarial district having frequent attacks of malarial fever, during one of which hemoglobinuria occurs, appears. In the absence of any means of examining the blood for parasites the administration of quinine was obviously indicated and in the case reported ten grains were injected four times over a period of two days. They could not have increased the hemoglobinuria in this case as it ceased within twenty-four hours of the last injection. Extensive bruising occurred at the site of the injections, which were given subcutaneously and not intramuscularly. In all cases of severe malaria there is a great liberation of hemoglobin which is precipitated in the form of yellow pigment in the liver. This liberation of hemoglobin cannot be from the infected corpuscle as it is far in excess of the number of infected corpuscles, continues after no parasites can be found in the blood, and non-infected parasites are found deficient in hemoglobin. This bore out Sir Patrick Manson's theory that part of the hemoglobin only is derived from these infected corpuscles which when sporulation occurs, set free some toxin which is able to liberate hemoglobin from uninfected corpuscles. This would account for the continuation of the hemoglobinuria when there were no parasites in the blood.

*The British Medical Journal, August* 5, 1905.

**An Experimental Contribution to the Treatment of Cholelithiasis.**—William Bain describes experiments undertaken by him on dogs to ascertain the changes undergone by gallstones introduced into the normal gall-bladder, and the fate of such calculi where cholelithiasis was artificially produced. He also administered various remedies to the dogs, in hope of finding one useful to the human being. The amount of cholesterin in the normal bile is small, 0.5 per cent., but in diseased conditions it is secreted in much larger amounts. In his experiments he opened the gall-bladders, soaked up the bile, inserted the stones, and closed the bladder and abdomen. If he desired to produce cholelithiasis, he injected a culture of bacillus coli communis in decinormal salt solution before closing the bladder. In general the dogs increased in weight after the operation. The results show that the normal gall-bladder will dissolve calculi in about nine weeks' time. Hence we should aim to render the gall-bladder aseptic in order to obtain this normal solution of calculi. Where cholelithiasis is set up the gallstones do not disappear, although they are reduced in weight.

**Professional Relations Between Spa Doctors and their Brethren.**—Albert Mouillot gives some very sound advice as to the best way of maintaining pleasant professional relations between the family physician sending his patient to a health resort and the medical man who takes charge of the patient while there. When the patient is sent by his family physician, the name and address of the practitioner to whom he is sent should always be given to the patient and a letter should be sent to the physician by post describing the case. No suggestion as to the treatment should be given to the patient, and wherever possible it should be left to the judgment of the spa doctor. Such a letter should not be given into the hands of the patient, as is may never be delivered. If the patient makes an appointment a few days ahead with his future physician, it will insure him a prompt opportunity of consultation. When these precautions are not carried out the patient frequently goes to incompetent persons for advice in the choice of a physician, or failing to see the one desired promptly, goes to another to save time. The family physician never receives any answer to his letter, and never gets any proper account of the treatment received. If no letter is written by him, or it does not correspond with what has been told the patient, a thousand unpleasant little incidents may occur in the line of apparent conflict in the mind of the patient between the opinions and statements of the two medical advisers. The time during which treatment is to be given should not be limited by the family physician, as the period necessary depends much on how the patient responds to treatment. The duties of the spa doctor are more strictly ethical. He should acknowledge the receipt of the letter describing the patient's case, and should write in full when treatment is finished. It is important not to appear to differ in diagnosis from the sender of the patient, and if anything unexpected is discovered, to communicate with the sender before telling the patient. The responsibility of the spa physician is not that of a consultant, and ends with his last treatment, whenever the patient is sent by a city consultant. If, however, he is sent by the family physician, the latter may desire advice as to future treatment in the line of that given at the health resort. Such advice should never be given to the patient himself. When patients come unrecommended and of their own initiative the case is quite different. Here the family physician need not be communicated with, except at the request of the patient, or on his own request after the patient returns home. You may suggest that, if your treatment is to be continued by the patient on his return, it be done with the concurrence of his physician.

*Berliner klinische Wochenschrift, July* 24, 1905.

**Diseases That Precede Carcinoma.**—E. v. Bergmann describes a number of his cases in which it was possible to determine some abnormal condition which had given rise to the development of carcinoma. Scars following burns or other extensive injuries are often the seat of malignant degeneration. Paget's disease of the nipple is another condition that precedes carcinoma, but it is a much rarer lesion than is usually supposed, for, out of a thousand cases of malignant growths of the breast treated by the author, only seven or eight of Paget's disease were found. He then mentions the carcinoma of chimney sweeps or tar workers, and next discusses at some length psoriasis of the tongue as a forerunner of cancer. This is a more frequent starting point of carcinoma than is generally recognized, and the author considers belief in a possible syphilitic origin of the condition as unfounded. Lupus is also an occasional precursor of cancer, and birthmarks form a frequent starting point for it. Every carcinoma of the extremities is secondary to some abnormal condition of the skin, such as scars, sinuses, ulcers, eczema, seborrhea, warts, moles, or birthmarks. The pigmented moles are an especially frequent seat of malignant deterioration.

**The Precipitin Reaction in Carcinoma.**—Kelling makes a vigorous reply to the recent communication of Fuld, who repeated Kelling's experiments with negative results. He ascribes Fuld's failures to improper technique, and gives details of the proper method at great length. He also reports tests on a series of one hundred cases. Thirty-three of these proved not to be carcinomatous, and all gave a negative reaction. Sixty-seven were undoubted cases of carcinoma, thirty-eight of these were negative, and twenty-nine gave a positive reaction, twenty-two responding to extracts of hen or hen embryo albumin, four to extracts of pig or pig embryo albumin, and three to extracts of sheep albumin. A large number of these tumors were tested after removal, and the proper reaction always ob-

tained. Kelling reiterates his former assertions, and maintains that there are cases of carcinoma in which the blood contains precipitins that have a distant relationship to albumins foreign to the human body. These reactions do not occur in other diseases, and when they are obtained with distinctness they permit a positive diagnosis of concealed carcinoma.

**Laryngeal Tuberculosis and Pregnancy.**—Kuttner gives an exhaustive study of this combination and concludes that the prognosis of diffuse tuberculous laryngitis occurring during pregnancy is extremely unfavorable. The mortality of children born of mothers suffering from this disease during gestation is very high. In consideration of these facts laryngeal tuberculosis is in principle a justifiable indication for the interruption of pregnancy, but this is permissible only when it appears to be the only possibility and offers some probability for the safety of the mother. Experience has shown that the induction of abortion in the later months of pregnancy does not offer very favorable prospects. Under these conditions, if the case is not already hopeless, tracheotomy may give a chance.

*Münchener medizinische Wochenschrift, July 25, 1905.*

**The Etiology of Croupous Pneumonia.**—Schottmüller describes six cases in which, although the symptoms produced were those of a typical croupous pneumonia, the disease was caused not by the pneumococcus but by a special organism, which he terms the streptococcus mucosus. When grown on solid media, this organism forms diplococci, which occur in chains of ten to fourteen members. The separate members are 1.5 $\mu$ in diameter, are rounded, and provided with a gelatinous envelope, which becomes visible in stained preparations. The coccus is positive to gram, and grows best at 37° C. On agar, after twenty hours, a clear, slimy, shiny gelatinous scum is formed. These characteristics are constant, and are maintained through successive generations. The author, therefore, agrees with Weichselbaum's opinion that the pneumonic virus is not a uniform agent, and that so-called lobar pneumonia may be caused by a number of different sorts of bacteria. These are, the pneumococcus of Fränkel, the diplobacillus of Friedländer, and the streptococcus mucosus. The streptococcus of erysipelas can also produce lobar pneumonias, but both clinically and pathologically these differ from the true type. The differentiation of the various bacterial inciting agents is of importance in making attempts to cure the disease by serum treatment.

**Inflammatory Fatty Tumors in the Knee and Tarsal Joints.**—Gaugele says that Hoffa, about a year ago, described a form of fatty new growth of synovial membrane of the knee, which was the cause of stiffness and disability. Becker investigated the matter further, and found that the process was by no means simply a hypertrophic one, but that it was a true inflammation of the fatty tissue of the synovial membrane. Gaugele describes a case in which complete relief was given to a disabling, painful affection of both knee joints that had resisted all the ordinary means of treatment, by excision of large masses of fatty tissue. Three other cases were subsequently treated in the same way, with equally satisfactory results. The author was led to apply the same reasoning to two cases of obstinate flat foot that presented slight swellings at the outer side of the foot below the mallcolus. On opening the joint in each case a lipomatous growth was found, the removal of which was followed by relief of the symptoms. The author also suggests that joint affections in other parts of the body that have been attributed to various obscure conditions may depend on inflammatory, fatty growths in these situations.

**The Treatment of Nasal Suppuration in Children by Aspiration.**—Sondermann says that the obstinacy of nasal discharges in children as well as in adults often exhausts the patience and the resources of the physician. In addition to suitable local treatment, the pharyngeal tonsil is usually removed, but this as well as other operative work about the nose nd throat may not lead to a cure of the rhinitis. He has perfected a plan of treatment which has given him excellent results and which he warmly commends. A face piece is used which fits the nose closely and is provided with a suction apparatus. The patient is desired to say "e," by which means the nasopharynx is shut off, and at the same time suction is made. All the secretion is in this way drawn out of the recesses of the nares, and even from the accessory cavities. In addition to the cleansing effect, the local hyperemia produced contributes towards bringing about a cure. In dealing with little children, some tact is often necessary, but one can always succeed with patience, and, as the procedure is not painful, the patients do not object to its repetition, and often learn to carry out the manipulation themselves. The frequency with which it should be repeated depends on the amount of secretion, but even in severe cases it is not necessary at first to aspirate oftener than four to five times daily, and the frequency may be rapidly reduced. The secondary effect of the treatment, that the author has repeatedy seen, is the cure of an obstinate cough, which was not based on any pulmonary lesion, but apparently was dependent on the nasal discharge.

*Deutsche medizinische Wochenschrift, July 27, 1905.*

**Experimental Observations on Sterilization of the Skin.**—Vogel, who is Bier's assistant, was led to make experiments with the hot-air apparatus devised by the latter, in connection with the question of sterilization of the skin. The consideration that has of late occupied investigators in this field has been the ability of the various methods in use to reach the bacteria concealed in the deeper layers of the skin, especially in the sweat glands. the author conducted his experiments by making cultures from his hands after sterilization, and again after they had been subjected to active sweating in the hot air box for half an hour. In this way it was found that, even though the cultures made before the sweating remained sterile, the hot-air treatment brought large numbers of bacteria to the surface in almost every case. The hot-water-alcohol-bichloride method was found more effectual than the soap-solution method of Mikulicz, and if the hand was disinfected in the former manner, sweated one-half hour, and redisinfected, a second sweating of one-half hour failed to bring to the surface any germs. While it is impracticable to apply the sweating procedure as a routine measure in every-day work, the author believes that it will furnish a valuable addition to the experimental methods of studying hand disinfection, and will also prove useful in some phases of operative work, both for preparing the patient's skin and that of the operator, as, for example, in hernias and in joint operations, when every possible precaution must be taken. Although the experiments seemed to indicate that the hot-water-alcohol-bichloride method was much superior to the soap-solution plan, the latter is still retained in Bier's clinic, first, because it has given good results in the past, and it is certain bacterial asepsis is a different quantity from surgical asepsis, and second, because it improves the condition of the skin, whereas the bichloride is damaging to the hands. For those who can stand it, however, the latter method is the safer one.

**An Apparatus for Pneumatotherapy in Heart Disease.**—Herz has devised an apparatus by means of which it is possible to accomplish what he calls endomassage of the heart. It consists of a mouthpiece through which the patient breathes, connected with an interrupting device. This consists of a toothed wheel against which a lever actuating a valve in the breathing tube impinges, so that as the wheel is turned the air tube is rapidly opened and shut off. By this means marked changes in the air pressure in the lungs are caused through the alternate rarefaction and compression of the air inhaled. The blood pressure in the pulmonary circulation is thus increased, and the auricles are better filled, while at the same time the mechanical pressure of the lungs upon the heart as a whole reacts very beneficially upon it. The author has employed the apparatus in a great many cases, principally of muscular weakness of the heart combined with arteriosclerosis, and is much gratified with the results. Both the physical signs and the subjective symptoms underwent marked improvement, and the patients were enabled to perform a greater amount of muscular work than before.

*Annals of Surgery, July 1, 1905.*

**Ligature of the Innominate Artery.**—The elaborate paper of W. Sheen is a study of this operation from the earliest times to the present, and includes the history of a successful personal case, the latter being the eighth on record. Only the author's general conclusions can be quoted here. These are: (1) That in properly selected cases ligature of the innominate is a reasonably safe and undoubtedly useful operation. (2) That suitable cases are those in which the aneurysm is of a circumscribed, globular character, and the general condition of the patient is otherwise good. That unsuitable cases are those in which the aneurysm is what is commonly called fusiform, but is really often nothing more than part of a general arterial dilatation, and in which there are marked signs of general arteriosclerosis with accompanying visceral disease. (3) That the maintenance of asepsis is the main factor in obtaining a successful result. (4) That the incision should be central with horizontal and vertical division of the manubrium, if necessary. (5) That the carotid should be tied as well as the innominate. (6) That silk is the best ligature material. (7) That some amount of injury to the inner coats is probably necessary to insure occlusion, but that with aseptic conditions such injury does not matter. (8) That two ligatures should, if possible, be placed round the vessel, the first turn of the proximal ligature being held tight, so as to keep back the blood while the distal ligature is completely tied. (9) That the use of a drainage tube is inadvisable. (10) That, as a study of the recorded cases shows, next to sepsis, some cerebral

lesion has been the most frequent cause of death after operation, it would be well for future operators to consider the advisability of tying the carotid about a fortnight before the innominate. (11) That "Valsalvan" methods of treatment immediately prior to operation are inadvisable.

**The Surgical Treatment of Tuberculous Cervical Lymphnodes.**—This subject receives an elaborate consideration by C. N. Dowd, whose paper is fully illustrated by photographs of patients and dissections. He gives the following summary: (1) Tuberculosis of the cervical lymphnodes is apparently due to infection received from the fauces, pharynx, or nasal mucous membrane, in the great majority of cases (86 per cent. in this series). (2) The disease shows a tendency to extend to the lungs and other internal organs. Statistics indicate that such extension occurs in one-quarter to one-half of the patients from whom the nodes are not removed. (3) Entirely apart from its tendency to infect other organs, the disease is very tedious, causes great discomfort and disability, and leaves disfiguring scars. (4) The thorough removal of the diseased nodes by operation has given better results than any other method of treatment which the writer finds recorded. (5) The records of operations justify the following assurances: (*a*) In favorable cases: Safety of operation (many operators reporting more than 100 cases without mortality); a scar which is hardly to be seen; probable confinement to bed of two or three days; the wearing of a bandage or dressing from one and a half to three weeks; freedom from recurrence in about 75 per cent., and ultimate recovery in about 90 per cent. of the cases. (*b*) In the less favorable cases: Safety of operation; less disfigurement from scars than discharging sinuses will cause; freedom from recurrence in 50 to 55 per cent., and ultimate cure in 70 to 75 per cent. of the cases. (6) Transverse incisions, either in the neck creases or parallel to them, are usually to be made. They should be so placed that the fibers of the facial nerve will not be cut. A vertical incision back of the hairline is occasionally helpful. Extensive incisions are necessary for the far advanced cases. (7) Every precaution should be taken to preserve the normal structures of the neck. (8) It is not feasible to divide the cases into groups, some suitable, others unsuitable for operation. Every patient with tuberculous cervical lymphnodes should be operated upon unless there is a particular reason to believe that the operation would not be endured.

**Drainage in Diffuse Septic Peritonitis.**—Van Beuren Knott emphasizes the following points: (1) Operations for diffuse septic peritonitis should be made as quickly and with as little manipulation as it compatible with thoroughness. (2) Evisceration, partial or complete, greatly increases shock and the prospects of a fatal result. (3) The generous use of clean, hot water will most thoroughly cleanse the infected cavity with the least traumatism. (4) Drainage is simplified by collecting the peritoneal fluid at one point where drains may be easily placed. The elevated head and trunk posture followed by the gravitation of fluid to the lower pelvis best accomplishes this. (5) Results following the surgical treatment of diffuse septic peritonitis will be improved should each individual operator adopt some definite form of procedure in such cases, which, being well understood by operator and assistants, may be methodically, speedily, and thoroughly carried out.

**Surgical Treatment of Chronic Mucomembranous and Ulcerative Colitis, with Special Reference to Technique.**—J. E. Summers, Jr., discusses the various operative procedures which have been followed in recent years in this class of cases. His personal experience comprises eight cases, exclusive of mild catarrhal conditions of the cæcum and appendix due to displacement of the right kidney. In four the Gibson operation has been done, and two of these have had, in addition, the ileum divided, the lower segment being occluded and the upper being implanted in the sigmoid flexure of the colon. The Maisonneuve method was followed in one instance. In another a sigmoid ulcer was excised. In still another urgency of operation was determined by an intussusception of the lower ileum, resulting probably from the antiperistalsis in the colon. Seven of the eight patients recovered. The cause of death in the fatal case is not definitely stated.

**The Treatment of Congenital and Acquired Luxations at the Shoulder Joint in Childhood.**—R. Whitman finds the essentials of successful treatment of these cases to consist of (1) complete overcorrection at the time of operation, (2) fixation for a sufficient time to assume the stability of the new articulation by accommodative changes within and without the joint, and (3) persistent after-treatment. The latter consists of daily passive forcible movements to the extreme limits in the directions formerly restricted, namely, outward rotation, backward extension and eventually abduction of the humerus and supination and extension of the forearm.

*French and Italian Journals.*

**Treatment of Migraine and Cannabis Indica.**—G. Carron de la Carrière give us an account of this method of treating migraine, which he has found very successful. It consists of neuroarthritic constitutional remedies, treatment for whatever organic or functional symptoms may be troublesome, and prevention of the crises. The first indication is met by a strict dietary; no alcohol, pure water and hot tea infusions, the only drink; beef, mutton, and chicken for meats; all vegetables that are not acid; for dessert, milk puddings, cheese, fruits, ripe and soft, or cooked. When crises are frequent a modified milk diet, without meats, with rice, tapioca, mashed potatoes, etc. The second means of fulfilling this indication is by the use of cannabis indica. It is given in pill form, one and one-half centigrams morning and evening, taken regularly for months and years, then intermitted and renewed for a month or two at a time, at periods of great fatigue. It is also useful for persistent dull headache lasting continuously. It must be taken regularly. The author begins with a small dose, and increases it up to the point of benefit or intoxication, having never produced a habit or bad symptoms. The third measure is the hot douche, tonic, revulsive, and sedative. He uses a broken spray, not douching neck or head, increasing in coolness, and ending with the feet. This must be taken daily for one or two months. The second indication is subserved by attention to digestive, uterine, or eye troubles. At the time of a crisis we may put it off by the hot douche and rest, the douche long and very sedative. When the crisis has set in we can only relieve pain by applications of chloroform and menthol, hot cloths, and sedatives. Each year the patient should visit an appropriate bath establishment and take a course of treatment.—*La Pressc Médicale*, July 19, 1905.

**Therapeutics of Tuberculous Lymphoma of the Neck.**—D'Este has treated many cases of tuberculous lymphatic glands in the neck by different methods. Some of them have been simply extirpated, without any medical treatment; others have had simple medical treatment, while a third class have had the two methods combined, the glands being removed and removed and then the treatment continued by the use of iodine. The combined method he considers much the most effective, giving a better and firmer scar and leaving the patient in better physical condition, with less liability to recurrence. Simple medical treatment is most unsatisfactory. The iodine he uses in doses of one centigram by injection at the beginning, and increases it to 5-6 centigrams at each dose. Less radical intervention than total excision is useless; simple opening of the abscesses and scraping are without effect.—*La Riforma Medica*, July 15, 1905.

**Autogenous Regeneration of Isolated Nerve Trnnks.**—A. Perroncito, from his experiments concludes that he has demonstrated that nerve fibres in trunks isolated from the nerve centres after a time, instead of undergoing autogenous regeneration, independently of the centres, grow from the central stump. He has seen the new-formed nerve fibres advance from the extremity of the central stump through the tissues, and with a very complicated path join the peripheral stump, perhaps finding their way through a muscle. A question intimately connected with that of autogenous regeneration, is the question of lack of continuity. He has demonstrated that all reports that go to demonstrate lack of continuity are due to errors of observation, and the application of insufficient methods, since the fibrillæ regenerate continuously, more rapidly than was supposed.—*La Riforma Medica*, July 15, 1905.

**Heredity, Biological and Psychological.**—Madeleine Pelletier draws our attention to the theory of Dantec, who believes that we should seek in histology an explanation of heredity. The ovule produces the same kind of an organism that it came from. The infant must resemble his parents because he is composed of the substance of his parents, a substance particular and different from other men. The form of the body is the expression of the equilibrium of the substance. The conception of heredity as a chemical phenomenon enables us to comprehend how that heredity can be an absolute law. Man is not only the product of a fertilized ovule; he is also the result of the combination of the substance of that ovule with exterior circumstances. Heredity does not transmit all the characters of the parent, and the child is never exactly identical with the parent. It is easy to comprehend, then, how mutilations are not transmitted. Alcohol, syphilis, and other poisons, acting chemically, are transmitted; so also good hygienic conditions, good influences may bring to the organism modifications transmissible by heredity. Profound chemical influences, acting quickly, are quickly transmitted; those that are feeble, and act slowly are transmitted in the course of generations. Simple mechanical modifications are not transmitted at all. If the influence is only temporary it has no inheritance. Such influences as acute diseases are not transmitted.—*La Médecine Moderne*, July 19, 1905.

# Book Reviews.

The Pharmacopœia of the United States of America. Eighth Decennial Revision. By the Authority of the United States Pharmacopœial Convention Held at Washington, A. D. 1900. Revised by the Committee of Revision and Published by the Board of Trustees. Official from September 1, 1905. Philadelphia: P. Blakiston's Son and Company, Agents, 1905.

Some of the changes in the new Pharmacopœia have already been noticed in the Medical Record, but the revision has been a very radical one, and the alterations are too numerous to be discussed completely in even a long review. For the most part, they appear to be in the direction of simplicity and practicability, and will no doubt be viewed with approval by both physicians and pharmacists. Some important changes have been made in terminology, such, for example, as the substitution of fluidextractum and fluidextract for the corresponding older Latin and English terms; acidum arsenosum has become arseni trioxidum; carbolic acid is phenol; spiritus glonoini has been changed to spiritus glycerylis nitratis; zinc valerianate has been abridged to zinc valerate, etc. It is gratifying to note that the Committee of Revision has decided to retain the terminal "e" in the names of the alkaloids, the halogen compounds, etc., and the reason given for the position, viz., that "it was not deemed wise or safe to sacrifice this distinctive method of designating powerful substances used as medicines," is perfectly rational. The most radical innovation, perhaps, is the admission of a few of the synthetic products, whose widespread use certainly justifies their official recognition, and of formulæ reproducing with more or less accuracy several commercial preparations. The addition of the average dose paragraph to each description is a decided advantage, though omission of the list of preparations which formerly occupied the corresponding position seems less well advised, as it formed a useful system of cross-referencing.

The articles dismissed can all be easily spared, and it is a matter for congratulation to find that the additions are not quite so numerous as the omissions. The paper and typography are more pleasing than those of the preceding revision, and the former binding was so thoroughly bad that this can hardly help being better. Some oversights are inevitable in so complicated a work, and they are not lacking in this revision. It is strange, however, that no one's eye was caught by the fact that although resin cerate has been changed to rosin cerate, the old form of spelling appears twice in the formula for turpentine liniment on page 257.

The new Pharmacopœia, as is announced on the title page, becomes official on September 1, 1905.

The Travelers' Handbook. A Manual for Transatlantic Tourists. Compiled by Josephine Tozier, Author of "Among English Inns." New York and London: Funk & Wagnalls Company, 1905.

Even the seasoned old globe-trotter will find many valuable suggestions in this well thought-out little book, while as for the tyro, the wonder is that his interminable questions did not result in some such comprehensive solution years ago. Certainly, after reading it there will be no excuse for certain errors now all too common, such as the carrying of luggage intended for a brief stay in London or Paris, but irresistibly suggesting a desert exile, and so on. Medical men journeying to Europe to attend congresses, or those going for a longer period of study, should not fail to make this handbook a part of their kit, for it answers all the questions with which they seethe, and will reduce the wear and tear of their trip to a minimum. In fact, it is only after reading even the index of Miss Tozier's book that we realize how much of the fatigue of travel is traceable to the thousand and one minor details as to which we are uncertain. A wide distribution of this handbook is all that is necessary to make the interrogative traveler like unto the dodo. It may be added that the little work makes no claim to encroach upon guide-book ground, but is emphatically what it calls itself, "The Travelers' Handbook." It is an almost indispensable companion to "The Pocket Guide," or the more voluminous Baedekers, for any one contemplating a trip to Europe.

Addresses and Other Papers. By William Williams Keen, M.D., LL.D., F.R.C.S. (Hon.); Professor of Surgery, Jefferson Medical College, Philadelphia; Membre Correspondant Étranger de la Société de Chirurgie de Paris; Membre Honoraire de la Société Belge de Chirurgie; Ehrenmitglied der Deutschen Gesellschaft für Chirurgie; Honorary Member of the Clinical Society of London, etc. Illustrated. Philadelphia and London: W. B. Saunders & Company, 1905.

This volume consists of seventeen addresses, six papers, a lecture and an oration. The subjects treated cover a variety of topics, historical, educational and scientific; some have a purely local interest, while others will appeal to a wide circle of readers. The first address, on "The Early History of Practical Anatomy," is the longest, and perhaps the most interesting in the volume. There are two papers (or, rather, a paper and an address) on "Vivisection," which will well repay perusal, and which appeal to the laity even more than to the physician. "Progress in Surgery" is the title of two papers written at an interval of ten years, and which attracted some attention when they first appeared. The above are the papers that have specially appealed to us; but all are worth reading, and the volume will serve as a first-class companion during an idle half-hour, and will make an attractive addition to the literature in the waiting-room.

A Syllabus of Materia Medica. Compiled by Warren Coleman, M.D., Professor of Clinical Medicine and Instructor in Materia Medica and Therapeutics in Cornell University Medical College; Assistant Visiting Physician to Bellevue Hospital. Second Edition. New York: William Wood & Company, 1905.

The addition of twenty pages on toxicology, and the correction of a few errors which were in the former edition constitute the only changes which have been made in this little volume. The book will be useful to the unfortunate student who has to learn all about a host of drugs and preparations, not more than a small percentage of which he will ever use.

Enlargement of the Prostate. Its History, Anatomy, Etiology, Pathology, Clinical Cases, Symptoms, Diagnosis, Prognosis, Treatment, Technique of Operations, and After-Treatment. By John B. Deaver, M.D., Surgeon-in-Chief to the German Hospital, Philadelphia, Assisted by Astley Paston Cooper Ashhurst, M.D., Surgeon to the Out-Patient Department of the Episcopal Hospital, Assistant Surgeon to the Orthopedic Hospital, and to the Dispensary of the German Hospital. Philadelphia: P. Blakiston's Son & Co., 1905.

This excellently and profusely illustrated book represents an important addition to the literature of prostatic enlargement. In the opening chapters the history and literature of the subject, the anatomy of the gland, and the pathology, etiology, and symptomatology of its diseased states are clearly and interestingly dealt with. In the diagnosis of prostatic enlargement Dr. Deaver advises against the use of the cystoscope; he thinks "that to advise the general practitioner, who may have need of a cystoscope once in five years, to insert it into the distorted, inflamed, and susceptible urethra of prostatics is to be guilty of great indiscretion." Surely, the author would not apply this objection to the trained cystoscopist, which every prostatic surgeon should be. Nor does Dr. Deaver practise what he preaches, for we find him advising the use of the cystoscope in order to differentiate tuberculous cystitis from prostatic enlargement.

The chapters devoted to the treatment of prostatic enlargement are excellent. The author's views, while radical, are tempered with the proper degree of conservatism. They represent the experience which he has gained from his own practice and from a close study of the work of others. The author believes that every prostatic should have a trial of catheter life, so as to ascertain which patients will be benefited by regular catheterism. "Because of the imperfection of its immediate result, and the uncertainty of its ultimate effect," he considers the Bottini operation to be but a makeshift, and to be employed only when no other treatment is applicable. The various sexual operations, he thinks, have fallen into deserved disuse.

Among radical operations, Dr. Deaver is a strong advocate of the suprapubic method of Freyer, though he considers that in selected cases, viz., those in which the prostate is atrophic, the perineal operation is to be preferred.

A good bibliography closes this excellent monograph, which all who deal with prostatics should read.

Les Indications des Interventions Chirurgicales dans les Maladies Internes, à l'usage des Médecins Praticiens. Par le Professeur Hermann Schlesinger (de Vienne). Traduction française de MM. les Docteurs Lichtwitz et Sabrazès, Professeur Agrégé, Médecin des Hôpitaux de Bordeaux. Paris: Vigot Frères, 1905.

This is the second volume of the French translation of Schlesinger's practical treatise on the indications for operative treatment of internal diseases. In this part the author takes up diseases of the liver and gall-bladder, the spleen, the pancreas, the kidney and its pelvis, and the bladder. Each of these subjects is treated of thoroughly from the standpoint of the surgeon ready to remove by the knife any lesion in an accessible organ which the medicaments of the physician have failed to disperse. Of necessity, the diagnosis of these lesions is thoroughly discussed, and the indications for and probable advantages of operative interference are carefully considered.

# Society Reports.

## BRITISH MEDICAL ASSOCIATION.

*Seventy-third Annual Meeting, Held at Leicester, July 25, 26, 27, and 28, 1905.*

(Special Report to the MEDICAL RECORD.)

(*Continued from page 281.*)

### SECTION OF OBSTETRICS AND GYNECOLOGY.

*First Day—Wednesday, July 26.*

The PRESIDENT, PROFESSOR H. R. SPENCER, of University College, London, welcomed Professors Wertheim of Vienna and Howard Kelly of Baltimore, who had come to take part in the discussion. He drew attention to the gynecological specimens in the museum, which were of unusual interest, and said that their collection was largely due to the efforts of Miss Garrett Anderson, one of the honorary secretaries of the Section. He then called on Professor Wertheim to open a discussion on

**The Diagnosis and Treatment of Cancer of the Uterus.**—Prof. WERTHEIM presented a table of 179 cases, with the results. All the cases had been followed up and their subsequent condition ascertained. Since 1898 he had operated on all cases by the abdominal route, removing connective tissue and glands. He performed preliminary disinfection and removal of the accessible portion of the growth by the cautery. The patient was then placed in the lithotomy position and a median abdominal incision made. The posterior layer of the broad ligament was divided and the ureters exposed and isolated from surrounding tissue. The anterior peritoneum was then incised and bladder separated, and the infundibulopelvic, broad, and round ligaments divided. The uterine vessels were then divided by pushing down a finger in front of them, lifting them up on the finger, and tying them. The ureter was then separated from the growth, the posterior layer of the broad ligament divided, and the rectum separated. The two lays of peritoneum were taken off as close as possible to the pelvic wall, after clamping, and the clamps were afterwards replaced by ligatures. The vagina was again cleansed with sterile gauze, and afterwards it was clamped to the isolated cancer and divided and separated below the clamps. To extirpate the glands, the peritoneal incision was prolonged upwards, and all enlarged glands up to the level of the division of the abdominal aorta and down to the obturator foramen were extirpated. The wound was treated in the following way: The cavity left by the removal of the tumor was carefully packed down to the vulva and the peritoneum sutured over, the abdominal wall being closed in layers. The gauze was removed on the fifth to the tenth day. The care of the bladder was most important, as it was frequently paralyzed for a time. The catheter was passed regularly, and the bladder frequently washed out with 3 per cent. solution of boric acid. It usually recovered its functions in a few days. Vesicovaginal fistula was a troublesome complication, and so was necrosis of the ureter, the latter sometimes requiring nephrectomy. This was required in three of his cases. To avoid necrosis of the ureter, it should not be completely raised. The duration of the operation was at first 2 to 2½ hours, but was now 1 to 1¼ hours. For a long time the mortality was 18 per cent., and death was mostly due to cardiac failure occurring 24 to 48 hours after operation. He now performed the preliminary cleansing of the vagina and scraping and cauterizing of the growth before beginning the anesthetic. The anesthetic used was Billroth's mixture. He attached more importance to the removal of the cellular tissue than to that of the glands. Since taking to the abdominal route the proportion of cases operated on had risen from 15 to 50 per cent., and he had operated on many cases which had been refected as too far advanced for operation elsewhere. Sections had shown that 28 per cent of the enlarged glands were infiltrated with cancer. The commonest site for infected glands was at the crossing of the iliac artery by the ureter. He emphasized the importance of women being taught that they should not neglect to seek advice for the early symptoms of cancer, and said that Winter had written a pamphlet for general distribution, having this object in view. He would limit vaginal hysterectomy to cancer of the body of the uterus and very early stages of cancer of the cervix, and he used the microscope in all doubtful cases.

Dr. HOWARD KELLY of Baltimore said that years ago he advocated extensive operation for cancer by the abdominal route, and he performed as wide an enucleation as possible. He had found that masses in the pelvis which he would have considered metastatic were always connected with the primary growth by a continuous band of infection; in operating he made a long slit below the ovary, exposing the ureter, and a most important point was not to separate this portion of the ureter from its attachments, but to push it along with the peritoneum. He inserted a ureteral catheter before commencing the anesthetic. He next ligated the infundibulopelvic ligament, then detached bladder and set ureter free in front, carefully ligating some large veins which lay just above it. He then exposed and tied the uterine vessels at their origin. He said we must never catch the ureter with forceps, but lift it gently with a blunt hook. He then divided the uterovesical ligaments. He used Wertheim's clamps, and cut across the vagina with the cautery. He said that it was especially important to pack off the whole wound area with numerous pieces of gauze. Ninety-eight per cent. of his patients had suffered from unusual bleeding from the vagina when first seen and 60 per cent. ought to have sought medical advice earlier. He thought that the causes of cancer lay largely in the moral field, viz., overwork, poor living, worry, etc.

Miss ALDRICH BLAKE of London read notes of sixteen cases of abdominal hysterectomy for cancer and presented a tabulated statement. She said that she had not considered involvement of the vagina a bar to operation, and as regarded fixation she had treated each case on its own merits; in only one case had she used preliminary cauterization of the growth, but in all she had washed out the vagina and packed it with iodoform gauze before commencing operation, removing the packing at the time of making the vaginal incision.

Dr. CUTHBERT LOCKYER of London said that among 4,000 cases seen by him in the out-patient room there were 85 cases of cancer, and 17 of these were operated on; in recurrent cases some good could be done by radium and high-frequency currents. The average age of his patients had been 46, and the average number of pregnancies to each case had been 7.

Mrs. SCHARLIEB of London had performed abdominal hysterectomy 15 times for cancer, with 3 cases free from recurrence for three years and upward afterwards. She thought that the field of vaginal hysterectomy for cancer would narrow more and more in the future.

Dr. CAMPBELL of Belfast recognized two classes of cases: (1) Where the growth spread early to the vaginal wall, and these were hopeless for operation by the older methods. (2) Originating in the cervical canal, which were more hopeful. In 50 cases of vaginal hysterectomy he had been unable to trace any remaining free after 3 years.

Dr. H. BRIGGS of Liverpool had operated for cancer of the body in 40 cases, and of the cervix in 109 cases, with 10 per cent. of freedom after 5 years in cervix cases and 30 per cent. in cancer of body. The mortality of the operation had been 3.7 per cent. The recurrence had most frequently taken place in the vaginal roof.

Dr F. J. MCCANN of London protested against the circulation of pamphlets such as had been mentioned amongst women, as likely to cause mental distress. He advocated supravaginal amputation of the cervix in doubtful cases of erosion and hypertrophy.

Dr. HERBERT SNOW of London thought that worry and

trouble were potent causes of cancer, and pointed out the great value of morphine in inoperable cases.

Dr. Inglis Parsons of London said that when the removal of the cancer was incomplete its growth was much more rapid afterwards. He advocated salicylate of soda in cases unsuitable for operation.

Dr. Rosenwasser of Cleveland, Ohio, had lately had an opportunity of seeing Wertheim's work in Vienna, and said that the necessary skill could be acquired by watching the work of a master and making experiments on the cadaver. In Wertheim's clinic the patients, if in bad condition, were first curetted to remove offensive growth, then kept in bed and fed up until fit for operation. He asked where the line would be drawn between cases suitable for vaginal operation and those in which abdominal operation was necessary.

Dr. Forbes Ross of London thought that irregularity of the arrangement of the cells in the gland acini could be recognized by the microscope in the very earliest stages of cancer.

Miss Mary Thorne of London considered that prolonged anesthesia added gravely to the dangers of the operation.

The President said that he considered Prof. Wertheim's the finest paper ever read on any cancerous subject, as the whole of the after-histories of the cases had been followed up. The conclusions to be drawn were that one can operate more safely and successfully by the abdominal than by the vaginal route.

Prof. Wertheim, in closing the discussion, said that he thought the statistics in his paper would refute the conclusions drawn by Prof. Olshausen of Berlin in a paper read by him at the last annual meeting of the association.

*Second Day—Thursday, July 27.*

**Fibroid Tumors of the Uterus.**—Dr. S. J. Cameron of Glasgow gave a lantern-slide demonstration illustrating some of the complications and degenerations of fibromyomata. Among the subjects demonstrated were the following: (1) Primary cancer of fallopian tube associated with a fibroid. The growth was in the peritoneal end of the tube, and Dr. Cameron considered that a hydrosalphynx had preceded the growth. (2) Sarcomatous degeneration of the fibroid from a woman aged 62. (3) Carcinomatous invasion of a fibroid. (4) Cystic degeneration in the line of the capsule of a fibroid. Dr. Cameron considered that this change, by interfering with the blood supply, led to calcification, and that the latter change was more common in broad ligament tumors. (5) Chronic twisting of pedicle in fibroid, leading to peripheral calcification and central liquefaction of the tumor. (6) Sections of the lower pole of a fibroid polypus, showing stratified squanous epithelium in place of columnar. (7) Telangiectatic change. (8) Adenomyoma in the uterus. This growth differed from a fibroid in having no capsule. (9) Malignant and cystic degeneration of an adenomyoma.

**High Limit of Pulse and Temperature Throughout the Normal Puerperium.**—Dr. Hastings Tweedy of the Rotunda Hospital, Dublin, read a paper with this title. He said that success in obstetric practice was more accurately gauged by morbidity than by mortality; even in the pre-antiseptic days the mortality was not always heavy. Thus in the report of the Rotunda Hospital for the year 1766 there were only three deaths among 611 women delivered; in the year 1877 the percentage of morbidity was 50; last year it amounted only to 3. He asked what were the physical indications of puerperal morbidity. Some time ago an elevation of temperature to 100-4 degrees was fixed as a limit. He found the pulse a more reliable guide, and that a very brief pyresia even much higher than this may mean nothing. He would fix the standard of normal recovery as a pulse of 90 and a temperature of 99 degrees Fahrenheit, and any rise above this should be investigated, though he would not consider it important unless the temperature and pulse remained above normal for at least twenty-four hours.

Dr. Byers of Belfast drew attention to the fallaciousness of thermometers and the importance of comparing pulse with temperature.

Dr. Corby of Cork laid stress on the importance of the patient sitting up in bed during the puerperium to suckle and for the purposes of defecation and micturition.

Dr. Buist of Dundee said that bacteriological investigations at his hospital had shown that there might be septic infection without rise of pulse and temperature.

Dr. R. Boxall of London said that the registrar's returns showed that there were as many deaths now from puerperal fever as there were in the past.

**A Standard of Puerperal Health.**—It was proposed by Dr. Buist, seconded by Prof. Byers, and resolved, *nem. con.*, "that it is desirable that a standard of puerperal morbidity should be arranged for lying-in hospitals, and that the Council be requested to appoint a sub-committee to consider the matter."

**Treatment of Cervical Cancer in the Last Two Months of Pregnancy, with Especial Reference to Vaginal Cesarean Section.**—Dr. Thomas Wilson of Birmingham read a paper on this subject. In the last two months the uterus with its contents was so large, he said, that until recently it had been considered impossible to remove it through the vagina, but Dührssen's method had cleared away this difficulty, and it was now possible to operate through the vagina even at the full term of pregnancy. In the last months of pregnancy in association with operable cancer of the cervix there was now therefore a choice of three methods of hysterectomy, viz., abdominal, vaginal, and combined. The relative advantages of these methods were discussed, and reasons given for preferring the vaginal route. Two cases were related in which operation was done at the eighth month successfully as regards both mothers and children. The uterus was incised in the mid-anterior line after separating the bladder; then forceps was applied and the child delivered, and afterwards the uterus was removed. The broad ligament was clamped by two pairs of forceps, which were left on for forty-eight hours. In conclusion, the author pointed out that the choice of operation in pregnancy would depend upon the method generally adopted by the operator in cases of cervical cancer. Even in the last months the operation of vaginal cesarean section was not a difficult one in suitable cases. The ultimate choice of operation in these cases would depend upon the remote results as regards recurrence of cancer, and until time had enabled these to be estimated and compared, the question of the best method of operating, whether by the abdominal or the vaginal route, must remain an open one.

Prof. Wertheim of Vienna said that he had operated six times for cancer complicating pregnancy—in one case at full term, in another at six months, and in the remaining four in the first three months. All the operations were done by the extensive abdominal method, and so far there had been only one case of recurrence; one case was done five years ago and another four years.

Prof. Spencer, the president of the Section, said that of all the cases in which the cancer was removed at the time of labor, only five were known in which there was not recurrence. The cancerous cervix dilated in a remarkable way if the whole circumference was not involved, and he advised delivery per vias naturales when possible, with operation later in the puerperium.

**The Influence of the Presence of Pus in the Female Urethra on the Prognosis in Obstetrical and Gynecological Cases.**—Dr. John Campbell of Belfast read a paper with this title. He said that this was especially important in pregnant women, for the pus was often of a very virulent character. The examination for pus would explain many obscure cases of puerperal septicemia. He had examined from this point of view 544 cases in private practice, and had found pus in the urethra or Skene's glands in 24 per cent.; in hospital practice the frequency was 29.4 per cent. In 120 parturient women he had found pus in the urethra in 18. Bacteriological examination was made in 100 cases,

with the following results: Mixed infection, mainly staphylococci, 96 per cent.; streptococcal infection, 6 per cent.; gonococcal infection, 2 per cent. The pus was squeezed out of the urethra after careful cleaning of the external parts. He strongly urged that every gynacological patient and every pregnant woman should be examined for pus in the urethra. Perchloride of mercury was the best solution for douching in these cases.

Dr. THOMAS WILSON of Birmingham said that the absence of gonococci was not a proof that the discharge was not gonorrheal in the first instance, as it was well known that the gonococci would die out, leaving the field in the possession of the other pus-producing bacteria.

Dr. BOXALL of London said that in order to avoid autoinfection from this cause at the British Lying-in Hospital, a douche of perchloride, 1-12000, was always given before, and sometimes after, labor.

Dr. CORBY of Cork read a paper on "Case of Fibroid of Ovary from an Hermaphrodite," the specimen being shown.

---

SECTION OF SURGERY.

*First Day—Wednesday, July 26.*

**Surgical Treatment of Non-Malignant Diseases of the Stomach.**—B. G. A. MOYNIHAN opened this discussion. He said that operation was required in certain conditions, and amongst these was acute perforating ulcer. With regard to the diagnosis of these cases, it would almost always be found upon inquiry that there was a long history of dyspepsia, and that it had been getting worse lately, so that it was not an acute ulcer that perforated, but a chronic ulcer; and the fact that there was an increase of the symptoms before perforation gave due warning in most cases of what might happen. With regard to lavage of the peritoneal cavity in these cases, it was not necessary in the cases operated on early; but in the later cases, where the general cavity was involved, it was, for then general peritonitis existed, and must be dealt with. Operation again was necessary in certain cases of hematemesis, notably in those in which there was recurrent hemorrhage of severe amount; and he would like to point out that in cases where hematemesis occurred there was usually a preceding warning, as in cases where perforation occurred, given by an increase of the symptoms. The multiplicity of ulcers of the stomach was far commoner than was usually supposed, and at the operation the stomach and duodenum should be examined for a second ulcer.

The medical treatment of chronic gastric ulcer often failed, and perforation or hemorrhage occurred; it was therefore clear that surgical treatment was safer, for the mortality percentage in gastroenterostomy, which was the operation he advocated, was only 3 per cent., and even this low mortality was capable of reduction, whilst 80 per cent. were permanently cured. Further, it appeared that chronic ulcer led to cancer of the stomach, for in some 60 per cent. of cases of cancer of the stomach there was a definite and positive history of preceding ulcer. He then said a few words upon hourglass stomach, a condition which he considered was very commonly overlooked, even at the operation. On one occasion he had seen a trifid stomach. The point necessary was to examine the whole stomach as a routine practise.

Dr. SAUNDBY, who came to the surgical section at the invitation of the president of the section, Sir Charles Ball, to speak on the subject from the physician's point of view, said that it was admitted by the surgeons themselves that in cases of atonic dyspepsia and in cases of neurasthenia, operation was not only useless, but even harmful, therefore the most important thing of all was diagnosis; and these cases where gastric ulcer was supposed to exist should be seen by a physician and a surgeon together, acting in concert. Further, he considered that the vast majority of cases of gastric ulcer were curable by simple medical treatment, especially by proper dieting; and that a very small field in these cases was left for the surgeon; at the same time he was far from failing to recognize the very low mortality which operation gave in these cases.

With regard to operative interference in cases of hematemesis, he considered it usually unnecessary, for the hemorrhage was, as a rule, perfectly amenable to medical measures.

As for ulcer leading to cancer of the stomach, ulcer was very common, and cancer very rare. He saw an average of only about one case in a year. So that any deduction based upon this theory was liable to grave error; and he declined to admit that operation in chronic ulcer was desirable with a view to saving the patient from cancer at some future date.

Prof. HARTMANN of Paris devoted the greater part of his remarks to the method of performance of gastrojejunostomy in which he differed but little from most English surgeons; he, however, considered that great care should be bestowed upon obtaining an aseptic condition of the mouth for some days before the operation was performed, and advised the washing out of the stomach with boiled water in cases where troublesome vomiting occurred after the operation.

Dr. J. M. T. FINNEY of Baltimore described at some length the method of procedure which he adopts in his operation of gastroduodenostromy. The most important point was the proper freeing of the pylorus and first part of the duodenum—the so-called *mobilisation* of the duodenum. He illustrated his method by diagrams. He had operated in 25 cases by this method, with only 3 unfavorable results. He showed drawings of cancer starting in the base of a hypertrophic ulcer of the stomach, which he believed to be the earliest stage yet recorded; and he considered that there was no doubt that cancer of the stomach did frequently start in these old chronic ulcers.

Dr. C. MANSELL MOULLIN said that an exploratory operation was justifiable in doubtful cases in which the disease failed to respond to medical treatment, and that a patient ought not to be left until he was in a hopelessly emaciated and weakened condition before operation was undertaken. In perforation by a gastric ulcer, operation must of course be undertaken. He had operated in 115 gastric cases of all kinds during the last five years; in many cases the patient's condition was so grave that he had operated only as a forlorn hope, but when a fatal result was inevitable without operation, it was clearly justifiable. In fact, it was only in three cases that he had refused to operate, on the score that the patient was too ill, and in all three the patient had died in 24 hours. In cases of hematemesis due to erosions and acute ulcer, the mortality was only 3 per cent. if no operation were performed; and he did not consider it necessary or advisable to operate unless the hemorrhage was very severe. In chronic ulcer, however, the mortality in cases of hematemesis was 16 or 18 per cent. or even higher, and he considered that an operation should be performed if one severe or two moderate hemorrhages occurred. It was not difficult to distinguish between the hemorrhage due to erosion and that due to chronic gastric ulcer. In the former there was little or no antecedent history pointing to ulcer, whilst in the latter the history of chronic dyspepsia and vomiting showed clearly the presence of an ulcer previous to the hematemesis. The operation must be commenced by finding the bleeding point and dealing with it. Gastrojejunostomy was not sufficient alone, but should be performed in addition when the condition of the patient allowed it. Gastrojejunostomy was also indicated in gastric ulcer accompanied by great pain, which was always due to adhesions, which were dragged upon by peristalsis. This was at once cured by allowing the food to pass rapidly out of the stomach into the intestine, and this object was attained by a gastrojejunostomy with a very large opening made in the cardiac portion of the stomach, so that the food at once fell through into the intestine.

Dr. F. S. EVE said that last summer he operated in three or four cases of acute erosions in which there was an antecedent history indistinguishable from chronic ulcer, and this added to the difficulty of the cases. He quite agreed

that acute cases due to erosions should be operated upon as a rule, but that in chronic ulcer with repeated hemorrhages operation was desirable. He had operated upon several cases of enteroptosis, and had sutured the stomach to the abdominal parietes. These operations of gastropexy had been very successful.

Dr. W. Bruce Clark said that in cases of perforative ulcer it was necessary to wash out the peritoneal cavity by the ordinary method of lavage—he had had the fluid tested in 10 or 12 early cases, and it had always been sterile; it should be sponged out, but the peritoneum did not require to be extensively dealt with. In later cases, when general peritonitis existed, lavage by means of saline injections of 14 or 16 pints into the subcutaneous tissues was desirable—a considerable quantity of the fluid was quickly effused into the peritoneal cavity, and so flushed it. In all cases a drainage tube should be put into the peritoneal cavity, but numerous drainage tubes were unnecessary. With regard to dealing with the ulcer, it should, where possible, be infolded, but in one case he only employed one stitch, and in another, in which the ulcer was high up under the diaphragm, and adhesions were forming, he left it without stitching at all, and merely drained the peritoneal cavity by means of a drainage tube; both patients did well.

Mr. R. Morison regarded pyloroplasty as a better operation than gastrojejunostomy; the latter being too serious an interference with the anatomy and physiology of the viscera. Patients submitted to the former operation were more vigorous and in better health than those submitted to the latter. He predicted that gastrojejunatomy would fail to maintain the high position in surgical opinion which it now occupied. He based his remarks on 28 cases of pyroproplasty.

Dr. F. C. Wallis said that four months ago he performed gastrojejunostomy upon a woman of 93 years for chronic gastric ulcer and she was alive and in good health now. He did not think that so much saline solution as 14 or 16 pints should be injected subcutaneously for the purpose of combating shock and flushing the peritoneal cavity by the indirect method; 8 or 10 pints was sufficient, and saved the patient from the risk of an inquest, with the verdict "found drowned."

Dr. C. B. Keetley said that the drainage of the pelvis was the key to the situation in dealing with the peritoneal cavity in these cases of perforative gastric ulcer, and a suprapubic incision should be made for this purpose. He regarded ascepsis of the mouth as most important in all these cases of gastric trouble.

Dr. E. Deanesley said that gastrojejunostomy was a very successful operation; although as a rule the ulceration caused no obstruction to the outward passage of the food contents, he thought that it caused spasm of the pyloric portion of the stomach if situated in that part of the stomach and gastrojejunostomy relieved this.

Dr. L. A. Bidwell preferred the anterior method of gastrojejunostomy, because in the posterior method the opening of the stomach was so fixed, especially by the fastening of the stomach at this point to the mesocolon, that the greater curvature of the stomach sagged over it, and the opening in the stomach was no longer the most dependent point; the success of the operation depended chiefly upon the complete and efficient drainage of the stomach. In performing the anterior operation the opening upon the anterior wall should be placed as low as possible near the lowest point of the greater curvature of the stomach. Pyloroplasty and Finney's operation he regarded as bad for the same reason, namely, that the drainage of the stomach was not thorough, since the new opening was not at the most dependent part.

Dr. A. B. Mitchell said that in operating upon a perforating gastric ulcer excision was unnecessary, for the ulcer rapidly healed after the infolding. He considered that the operation of stitching should, when the patient's condition allowed it, be combined with gastrojejunostomy, which placed the stomach at rest.

Dr. Moynihan briefly replied. He regarded Finney's operation as a very valuable one, but he had stuck to gastrojejunostomy in order that he might learn its best methods and the most advantageous way of performing it and managing the case. He thanked Dr. Finney and M. Hartmann for their interesting remarks, and all those speakers who had taken part in the discussion. He regarded pyloroplasty as of little or no value, and considered that the statistics of the operation showed that it ought not to be performed. In performing gastrojejunostomy he preferred the posterior method to the anterior, as did most other surgeons.

**Some Further Experiments on the Sterilisation of the Skin.**—Dr. C. Leedham-Green read a paper with this title. He found antiseptics in alcohol more efficient than aqueous solutions. Of all those in general use which he had tested, he found an alcoholic solution of perchloride of mercury the most efficient.

Dr. Pearson considered biniodide of mercury in 75 per cent. alcohol, with 25 per cent. of sterilized water added, an exceedingly valuable solution for sterilizing the skin.

**Statistics of Gastrojejunostomy.**—Dr. Atkins gave tables of the after results in 20 cases of gastrojejunostomy. Four he had been unable to trace; of the remaining 16, all had been much benefited and able to return to their work. The time of operation ranged from four years ago to one year ago. He also reported a case of gangrenous appendicitis, in which the patient had succumbed to acetonemia three days after the first onset of symptoms. He advocated operation at the earliest possible moment in all cases of appendicitis.

(*To be continued.*)

## THE PRACTITIONERS' SOCIETY OF NEW YORK.

*One Hundred and Ninety-sixth Regular Meeting, May 5, 1905.*

The President, Dr. Charles Stedman Bull, in the Chair.

**Operations for Procidentia Uteri.**—By Dr. William M. Polk. (See page 285.)

Dr. Beverley Robinson asked Dr. Polk whether, in the operation he had described, the ovaries were left. In a case that came under his observation last year, where the uterus and its adnexa had been removed, the patient had certain neurotic manifestations that eventually disappeared entirely.

Dr. Andrew H. Smith called attention to the fact that the conservative measures recommended in gynecological work at the present time were widely at variance with the very radical operation advocated a decade ago—the so-called normal ovariotomy, which consisted in removing the ovaries and leaving the uterus.

Dr. M. Allen Starr, in connection with Dr. Polk's paper, reported a case that had recently been referred to him by Dr. Henry Hun of Albany. The patient was a woman who had for a long time had a prolapse of the uterus, with cystitis and a considerable degree of incontinence of urine. In the course of time she developed a very peculiar gait, consisting of a short, rapid step, with irregular balancing movements and an overlapping of the knees, which had led two neurologists to make a diagnosis of spastic paraplegia, or lateral sclerosis. Dr. Hun did not concur in that diagnosis, and thought the peculiar gait was the result of the continual efforts made by the woman to keep her uterus from falling down. When Dr. Starr examined her, he found no evidence of organic disease. There was no anesthesia nor ankle clonus, and the gait was not truly spastic, although to a superficial observer it was rather suggestive of lateral sclerosis. Through her long-continued efforts to keep her uterus from coming down, the woman had developed this automatic or semivoluntary gait.

Dr. Polk, in reply to a question as to whether the operation he had described interfered with the function of the

bladder, said that, on the contrary, it rather aided it, and added to the efficiency of that organ. It was now an accepted notion to leave the ovaries in all cases of extirpation of the uterus, unless their condition imperatively demanded removal, on account of the influence of the ovarian secretion upon the nervous system. The speaker said he was not prepared to say how much good was accomplished by leaving the ovaries after removal of the uterus. He recalled one case, in an extremely nervous, hyperesthetic woman, whose symptoms, caused by a fibroma, were relieved by removing the uterus, leaving the ovaries; menopause symptoms were, however, intense, the presence of the ovaries seemingly being of no avail. The general rule, however, was to leave the ovaries if they were not diseased, but removal of the uterus largely robbed them of their circulation, and they would probably atrophy sooner or later. The same thing happened after vaginal hysterectomy for prolapsus uteri. The circulation was not restored, and atrophy of the ovaries occurred in the course of two or three years.

Dr. Polk said that during the ovariotomy craze, to which Dr. Andrew H. Smith had referred, gynecologists concluded to take the bull by the horns, and removed ovaries for the relief of various conditions which it was now known had no connection whatever with those organs. During that period hundreds of ovaries were no doubt uselessly removed, and very frequently the operation eventually left the woman a nervous wreck. The operation was frequently done for the relief of ovarian pains, particularly in young women, which it was now known were due to chronic endometritis, and which often readily yielded to curettage. It was even claimed by some that epileptic seizures could be relieved by removing the ovaries.

**A Case of Gonorrheal Arthritis and Endocarditis of Obscure Origin.**—Reported by Dr. A. Alexander Smith. The patient was a traveling salesman, 28 years old, who was admitted to Bellevue Hospital two weeks ago. The history obtained was that he had been on a drinking bout for the preceding fortnight, and during that time he began to suffer from pain in the right knee joint. The pain gradually became more severe, and when the patient entered the hospital the joint was swollen to about twice its natural size, and his temperature ranged between 102° and 103°. The case was regarded as one of single-joint rheumatism, and although a gonorrheal origin was suspected, there was no evidence of that disease, and the patient absolutely denied a gonorrheal infection. Forty-eight hours after his admission he developed an acute endocarditis, and within two days later an acute pericarditis. On admission the leucocyte count was 17,000; forty-eight hours later it was 21,000. The knee-joint was aspirated and found to contain pus. This was submitted to Drs. E. K. Dunham and Henry S. Norris for bacteriological examination, and both reported that it contained pure cultures of gonococci. The blood was also repeatedly examined, with similar results. In spite of this, the patient still denied that he had ever had a gonorrheal infection. His urethra was absolutely clear, and no gonococci were found in the urine.

Dr. E. G. Janeway said that in one of the children's hospitals in the city there had recently been reported a number of cases of gonorrheal endocarditis and other gonorrheal affections, in which the usual primary source of the disease was absolutely excluded.

Dr. Polk said that among children the disease could be easily disseminated by nurses and attendants, but this explanation would hardly be satisfactory in the case of adults.

Dr. A. Alexander Smith, in closing, said that as the man had been on a spree for several weeks, he might possibly have become infected without recollecting it, but, if so, he showed no evidences of it outside of the joint and heart affection. The symptoms of arthritis came on before any instrument had been introduced into his urethra.

**Joint Affections in Cerebrospinal Meningitis.**—Dr. Beverly Robinson said he had recently made an effort to have the value of salicin tested in the treatment of cerebrospinal meningitis, in which he had made the claim that it might be a useful remedy. Thus far the number of cases in which he had seen it employed were too limited to permit him to speak authoritatively on the subject. He inquired whether any of the members had met with cases of cerebrospinal meningitis complicated by joint affections. Two such cases had come under his observation.

Dr. George L. Peabody said he had seen only one case during the past winter in which there was any conspicuous joint involvement. In that instance the right knee joint was much swollen and very tender, and contained a great deal of fluid. It was not reddened. The patient, who was a boy of twelve years, recovered from his cerebrospinal meningitis, and the joint improved after a few days' application of cold compresses, and without the use of salicylates. Dr. Peabody said he had seen two cases—one during the present epidemic and the other a year ago—that had been diagnosticated as cerebrospinal meningitis, chiefly because of the headache and the rigidity of the neck, which proved to be cases of rheumatism, and the symptoms disappeared promptly under the use of the salicylates. The speaker said he had never tried salicin in cerebrospinal meningitis.

Dr. Robinson said he was convinced that salicin was a more efficacious remedy in the treatment of rheumatic affections than either sodium or ammonium salicylate, and it possessed the further advantage that it did not give rise to either head or heart symptoms.

Dr W. Gilman Thompson said there was a notable absence of joint symptoms in the adult cases of cerebrospinal meningitis observed during the present epidemic. There was also a notable absence of eruptions. It was therefore interesting that Dr. Holt had reported a number of cases of joint affections in the disease in children.

## THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

*Stated Meeting, May 8, 1905.*

The President, Dr. Thomas E. Satterthwaite in the Chair.

**Trachoma in Children.**—Dr. C. Cole Bradley read this paper in which he stated that trachoma in the children of New York City, and particularly in the school children, had occupied a prominent position in the public eye during the past two years, and had at last been recognized by the Board of Health as a decided enemy, to be fought as strenuously as the other contagious diseases of childhood. Two years ago, while the disease was not truly epidemic, it existed in a large and increasing proportion of the school children, and it was now a matter of history how ably the Board of Health met the situation. Hospitals were established for the treatment of the afflicted children, and a careful system of regular inspection was inaugurated. As a result of this supervision, the percentage of cases had been greatly reduced during the past two years. Trachoma might be defined as an inflammation of the conjunctiva, due to a specific organism, characterized by the development of hypertrophic areas, and followed by the formation of cicatricial tissue, with its consequent contraction. There was little doubt that it was caused by a specific organism, which had yet to be demonstrated. In this city, the male sex was more subject to the disease than the female. It was met with in two forms, acute and chronic. At first there were often no symptoms other than slight discharge in the morning; in other cases there was lacrymation, burning and itching of the lids, and sometimes sensitiveness to light. In the acute form the symptoms were very similar to those of a purulent ophthalmia. If the disease was unchecked, there was contraction of the palpebral slit, due to thickening of the upper lids, followed by the slow formation of cicatricial tissue, with its consequent contraction. The form seen daily in the children of New York was the soft follicular trachoma, and hence the difficulty of differen-

tiating between follicular conjunctivitis and trachoma. Some had claimed that the school children were suffering from an epidemic of follicular conjunctivitis rather than from trachoma, and had intimated that the strenuous efforts of the Board of Health were rather far-fetched and possibly unnecessary. In speaking of his treatment of trachoma, Dr. Bradley summarized it as follows: (1) The general use of sulphate of copper was not altogether harmless. (2) The use of a 1 per cent. solution of bichloride of mercury was harmless, and was equally as good in its curative results as sulphate of copper. (3) Copper citrate was apparently harmless, and devoid of the objectionable features of copper sulphate. (4) General anesthesia was unnecessary in the operation of expression. Cocaine hydrochlorate, in solid form, answered every requirement, and obviated the necessity of a hurried operation, with its frequent extensive laceration of lid tissue.

**Eczematous Affections of the Eyes of Children.**—Dr. John E. Weeks presented this paper. He stated that eczematous affections of the eyes of children were met with at any age after the first few months of life. The form was "moist" eczema. It affected the eyelids, the conjunctiva, and the cornea. It was found most frequently in children whose hygienic surroundings were poor, and in those who had been permitted to eat indiscriminately. The robust, as well as the poorly nourished might be affected. Children of the poor were more frequently attacked, but those of the wealthy were not exempt. In regard to the etiology of eczema of the eye, two factors were involved; one, a predisposition on the part of the tissue, or rather a susceptibility, which permitted the active factor to produce the specific disturbance; the other, the exciting cause, which appeared to be the staphylococcus pyogenes aureus, which found its way beneath the epithelium of the lid, conjunctiva, or cornea, and produced the elevations peculiar to the early stage of the disease. The symptoms of eczema of the lids were those of irritation occasioned by the development of the nodules and denuded areas. The treatment of the condition was both constitutional and local. The former consisted in correcting the diet and improving the environment of the individual, particularly in regard to hygienic conditions. Calomel, in small, frequently repeated doses (one-tenth of a grain, three or four times daily), continued for from two to four weeks, often produced excellent results. Care should be taken to avoid mercurialism. The local treatment consisted in freeing the lids of crusts by means of bland alkaline solutions, and applying to the surface a protective ointment, which might consist of the yellow oxide of mercury in the strength of one and a half to two per cent. Many of the cases did extremely well if calomel, in a thin layer, was dusted on the affected area after the crusts had been removed and the surface gently dried. When calomel was used in this way, the iodides should not be given internally. In eczema of the cornea, with involvement of the iris, atropine, in the strength of one per cent., might be instilled sufficiently often to keep the pupil dilated. The possibility of a recurrence should not be lost sight of, and preventive measures should be employed.

Dr. Francis Valk said he was inclined to take a more optimistic view of trachoma than did Dr. Bradley. From a clinical standpoint, these cases could be separated into two types, first, that known as "school trachoma," of follicular conjunctivitis, which he looked upon as rather benign in character, yielding readily to treatment, and rarely invading the ocular portion of the eye. The second form was the true glandular disease of the conjunctiva, which was very intractable, if not incurable. The speaker said he had never seen a case of true trachoma that he considered really cured, and it was this pernicious form of the affection that frequently led to pannus, entropion, and other disastrous sequelæ. In operating for trachoma, Dr. Valk said he preferred to do thorough expression under ether in preference to a local anesthetic. In order to prevent subsequent adhesions of the lid to the conjunctiva, he permitted immediate use of the eye after the operation. The subsequent treatment consisted of applications of silver nitrate, five grains to the ounce, to which he added one-quarter part of the sweet spirit of nitre; this seemed to exert a remarkably good effect on the ocular conjunctiva.

Dr. Richard Kalish said that in speaking of the statistics and treatment of eye diseases, we should separate institutional cases from those seen in private practice. By some, the terms trachoma and purulent ophthalmia were employed almost synonymously, and this had created a great deal of misapprehension and confusion. As to the communicability of trachoma, Dr. Kalish said the consensus of opinion among those who had most carefully investigated the subject was that it was not simply a local disease, due to an infection from some outside organism, but a local manifestation of a constitutional diathesis. Trachoma was not essentially a contagious disease, and the position taken by the Board of Health, declaring it to be such, and spreading broadcast the impression that a contagious eye disease was epidemic in New York City, was unjustifiable.

Dr. Alexander Duane said that in the treatment of eczematous affections of the eye, as well as in conjunctivitis and keratitis, both the local and general treatment were very important. As a local application, he depended largely upon calomel, dusted into the eye freely every other day or oftener, and in addition to this, particularly when the infiltration was marked, he used hot moist compresses, wrung out in plain water or boric acid solution, and applied every two or three hours for five or ten minutes at a time. When the irritation was pronounced, with blepharospasm and photophobia, he used atropine. He had never had occasion to use cocaine, and deprecated its employment, particularly as a routine home measure by the patient. Later on, when the irritation had begun to subside, he prescribed the yellow oxide ointment, beginning with one per cent., and gradually increasing its strength as the ulcerations became more sluggish. In the bad cases that went on to the formation of confluent ulcers on the cornea, he applied iodine directly to the surface, either in the form of the tincture, or in the 10 per cent. vasogen solution. Internally he favored small, repeated doses of calomel, continued for weeks or even months. If there was anemia, he gave the syrup of the iodide of iron, but the iodides should always be withheld when calomel was used locally. Proper dietetic and hygienic measures were also of the utmost importance.

Dr. John C. Lester favored the operative treatment of trachoma, and said he did not believe the disease could ever be eradicated by local applications of strong bichloride solution or similar remedies, which not infrequently gave rise to traumatic ulceration, entropion, etc. He thought the best treatment was by expression, squeezing out all the follicles, and then making one or two applications of a strong bichloride solution, followed by some antiseptic. In eczematous affections of the eye the hygienic and constitutional treatment should be instituted first, and the local treatment afterwards.

Dr. Silas F. Hallock said that in the treatment of follicular conjunctivitis and the milder forms of trachoma he had found a strong solution of tannin and glycerin very serviceable. True trachoma was usually very intractable, and expression was necessary, preferably under ether.

Dr. Charles W. Stevens said that certain races seemed to be immune from trachoma, and it was a curious fact that it was common among all races that had the mesocephalic type of skull, while among the brachycephalic and dolichocephalic types it was practically unknown, excepting as sporadic cases. This fact might have some bearing on the etiology of trachoma, as the type of skull had an important bearing on the axis of vision.

Dr. H. Davidson Saril thought that trachoma was increasing rather than decreasing in New York—at any rate, outside of the schools. The affection might involve the lower lid, or the upper, or both. He considered it intensely contagious. The best treatment was by expression, which should be done under a general anesthetic in young children;

under cocaine in adults. The question as to the identity of follicular conjunctivitis and trachoma was still *sub judice*, and there were certain borderline cases in which it was very difficult to differentiate between the two.

**Symptomatology of Acute Otitis in Children.**—Dr. Charles Gilmore Kerley presented this paper. He stated that acute otitis in the young was probably more frequently overlooked by the practitioner than was any other disease of children. This was through no fault of the physician, but because of the indefinite manifestations of the condition, and the faulty teachings as to its symptomatology. In most of the text-books on otology, pain was given as the most significant symptom of acute otitis, and was manifested in the very young by tossing the head from side to side, head-rolling, ear-tugging, crying out during sleep, pain upon manipulation of the ear—in fact, we had been taught that the most important and reliable symptom was some manifestation of pain located in the ear or in the adjacent structures. Dr. Kerley said that in 72 cases that had come under his observation, one symptom, and only one, was present in all, and that symptom was an elevation of the temperature above the normal. Every one of the children had fever. In those cases in which the otitis followed, but was not immediately associated with any preceding disease, which was the case in the majority, the temperature range showed no special characteristics. In some there was a morning drop and an evening rise. With but few exceptions, the otitis developed during the convalescence of an acute process elsewhere, and the ear involvement was suspected because of a persistent elevation of the temperature, for which no other cause could be discovered. In fifty of the cases, or 69 per cent., there was an absence of pain. In concluding, Dr. Kerley emphasized the fact that no examination of a sick child should be regarded as complete without a thorough investigation of the condition of the middle ear.

**Operative Interference in Diseases of the Ear in Children and Its Limitations.**—Dr. Arthur B. Duel presented this communication. He stated that in treating infants with aural disease, the attitude of the surgeon should be entirely different from that assumed toward an adult with a similar difficulty. From a diagnostic point of view one was dealing, in the case of an infant, with a lesion which was situated in a position that had entirely different anatomical relations. There was one large bony cell, the tympanum, connected by a wide passage (the aditus) with another bony cell, the antrum, lying, at this age, directly under the cortex, behind and above the tympanum, a position favorable for drainage. Dehiscences might exist in the tympanic and aural roofs, and one was certain to exist, namely, the Rivinian segment, which was so patent that pus, under pressure, often escaped to form a postauricular abscess before the drum was ruptured. In the recognition of ear trouble in infants, one had to go entirely on objective symptoms, and in the young child, peevish from pain or fear, statements regarding tenderness had to be discounted. Otitis was seldom present in infants or small children, excepting when complicated by adenoid vegetations in the nasopharynx, and usually by hypertrophied faucial tonsils as well. It was a frequent accompaniment of the acute exanthemata, whooping-cough, grippe, etc., and for that reason cases in which temperature alone could be looked upon as a sufficient cause for the mastoid operation were extremely rare. In every case of acute suppuration of the middle ear in infants and children, Dr. Duel said he would insist upon a very free incision of the drum membrane at the earliest moment, to insure the best drainage possible from the tympanum. If the lesion had appeared as a complication of pneumonia, the acute exanthemata, or some other affection which had seriously impaired the vitality of the patient, the operation, though very painful, should be performed without an anesthetic rather than to subject the patient to still further risk. When the child was strong and vigorous, and the local trouble was the only one manifest, humanity and thoroughness would suggest an anesthetic. When adenoids were present, the speaker said he had a growing conviction that they should be removed at the time of the paracentesis, provided the child was fairly vigorous, and was not suffering from serious concomitant disease. Otherwise, they should be removed as early as the general condition of the patient would permit. In regard to the indications for a mastoid operation, Dr. Duel said that on account of the anatomical relations in young infants, he would not operate on such patients if the subjective symptoms were the only ones to depend upon, excepting on the appearance of a postauricular abscess, unless symptoms of an alarming character, suggesting the involvement of the sinus or meninges appeared. In older children, however, where the cells beyond the antrum had begun to develop, and the involvement of which by a suppurative process meant that the sinus was in constant danger of infection, and where the danger to the patient was not so great from the operation itself, he was inclined to operate earlier. Up to five years of age, subperiosteal abscess often occurred early in the involvement of the mastoid; after five years it seldom occurred early.

Dr. James F. McKernon said he agreed with Dr. Kerley that a rise of temperature was one of the most important, and, in fact, often the only symptom of acute otitis in children, and it was especially significant of middle ear trouble when it remained elevated after convalescence from one of the acute exanthemata or other disease had set in. Pain, on the contrary, was a comparatively rare symptom of the condition in young children. After five years of age, pain became a more prominent symptom, but younger children rarely complained of pain in the affected ear, or showed any reliable manifestations pointing to it. In that class of patients, too, it was very difficult to determine whether the mastoid structure was involved simply from the standpoint of percussion and pressure. A more valuable guide in young children was an inspection of the walls of the external and middle ear canal. If the canal walls were more or less swollen, and its cavity quickly refilled with pus after careful cleansing, mastoid involvement should be strongly suspected. Dr. McKernon said he had never removed adenoids at the time of doing a paracentesis, and would probably hesitate to do so, although he saw no objection to it in an otherwise healthy child. Neither did he see any objection to the use of a general anesthetic unless there was a complicating respiratory condition.

Dr. Herman Jarecky said the satisfactory examination of the ear in young infants was not a simple matter. In operating on these cases, the speaker said he preferred ethyl chloride, used as a general anesthetic and applied with an ordinary mask; it was entirely effective, and he had found it simple and safe. He had never removed adenoids at the time of doing a paracentesis, and would prefer not to combine the two operations. Opening the ear drum in young children should be done early, as inflammatory processes extended very rapidly in these patients.

Dr. John Broadfoot Rae said he thought pain was a very constant accompaniment of acute otitis in children, but its evidences were easily overlooked. Often it was manifested by restlessness, or handling the affected ear would cause the child to wince. The speaker said he had never removed adenoids at the time of doing the ear operation, but he would not hesitate to do so in proper cases. A better time to remove them, however, was before the paracentesis was indicated. It might then serve as a prophylactic measure, and the local blood-letting might abort the attack. Postauricular swelling was an early symptom of mastoid involvement in young children, and one of great value.

Dr. Philip D. Kerrison said that at the Willard Parker Hospital over 300 cases of acute otitis were treated last year. The temperature seemed to be the most important symptom, and in many of them the only one. In a certain number of cases, however, there was no rise of temperature whatever. Of 648 cases of otitis observed between

1900 and 1904, 108 were cases of chronic suppurative otitis, and of that number 38 were in children under ten years of age. Of the adult cases, 36 gave a definite, reliable history of a chronic, persistent ear discharge which dated back to childhood. Thus 74 out of 108 originated in early childhood. These figures illustrated the frequency with which chronic otitis media, the most dangerous lesion of the middle ear, originated in early childhood, and the responsibility rested with the general practitioner and the otologist not only to cure the acute condition in children, but to prevent it from becoming chronic. Inasmuch as adenoids kept up the inflammation in the ear, it was a very sensible thing to remove them at the same time.

---

### Pathological Society of Philadelphia.

At a stated meeting held May 11, Dr. W. E. Robertson exhibited a specimen of "Disseminated Carcinomatosis," presenting clinically symptoms of pulmonary tuberculosis. After death the adrenal glands were found the seat of the primary lesion, while innumerable metastases were present in many organs. An infected gland had ulcerated into the trachea and the right lung was the seat of extensive invasion. Dr. Robertson exhibited also the lungs from a case of pulmonary tuberculosis. The one lung was almost entirely replaced by an enormous cavity, while the other was infiltrated and contained smaller cavities. Dr. W. T. Longcope read a paper entitled "Tuberculosis of the Thoracic Duct." He presented an analysis of 26 cases of the disorder and discussed the mode of origin, the symptoms, and the sequels. Drs. L. Pearson and S. H. Gilliland presented a communication entitled "Additional Experiments upon the Immunization of Cattle Against Tuberculosis." It was found that the immunity conferred by vaccination with tubercle-bacilli of gradually increasing virulence was the greater the more frequently and the more recently the inoculations were made and the shorter the intervals between them. Dr. R. C. Rosenberger read a paper on "A Study of the Mesenteric Glands Especially in Relation to Tuberculosis." The observations were made in cases of typhoid fever and of tuberculosis. Dr. H. R. Alberger presented a specimen of "Anthracosis of the Liver in Pulmonary Tuberculosis." The condition is exceedingly rare. Dr. Russell exhibited a specimen of melanosarcoma of the brain and lungs. The patient had had a melanotic sarcoma of the eye removed five years before death, and during his last illness had presented symptoms of tumor of the brain.

---

At a stated meeting held May 25, Drs. J. M. Anders and A. C. Callahan reported "A Case of Bilharzia Hematobium," and they demonstrated microscopic slides showing ova of the parasite. The life-story and the mode of dissemination of the parasite were described, together with the morbid anatomy and clinical phenomena to which its presence in the human body gives rise. In the case in question the ova were found in the centrifugated urine, which contained blood, and also in blood-clots discharged from the urethra. Dr. J. Funke presented a communication entitled "Thrombosis of the Superior Mesenteric Artery with Intestinal Perforation and Hemorrhage." He exhibited an illustrative specimen obtained from a patient who during life presented symptoms of intestinal obstruction, with the development of fatal peritonitis. On post-mortem examination there was found, in addition to the occlusion of the artery, a putrid peritonitis resulting from perforation of an ulcer of the ileum about one meter from the ileocecal valve. A second ulcer was present in the ileum, but this had not perforated. Dr. Funke discussed the etiology and symptomatology of the disorder. Valvular disease of the heart and atheroma of the vessels are the commonest causes. Infectious disease in the pelvis may give rise to venous thrombosis. The symptoms are generally those of intestinal obstruction with pain in the umbilical region, vomiting, and bloody stools. Dr. A. J. Smith presented a communication entitled "Hypertrophy of the Thyroid Gland in a Case of Hypotonia." The specimens came from a child 22 months old, presenting the rare condition of congenital myatonia, the muscles generally being enfeebled and flaccid during life, and after death exhibiting hyaloid degeneration. In addition the thymus gland was persistent and enlarged and it exhibited hyperplasia of the interstitial fibrous tissue and increase in number and enlargement in size of Hassall's corpuscles. Drs. J. F. Schamberg and R. Hirschler presented a communication entitled "Epithelioma of the Forehead Having Its Origin in a Papillary Nevus." The patient was a young man who had had a linear papillary nevus on the forehead since birth, and which exhibited increase in size and a tendency to ulcerate following irritative traumatism. A portion of the growth was removed and on histological examination was found to be epitheliomatous, the new process apparently originating from a hair-follicle. Dr. H. S. Wieder read a paper entitled "Intrahepatic Gall-bladder." He presented a specimen illustrative of this condition obtained from an infant and he referred to the few descriptions of the like anomaly recorded in the literature. The liver also presented abnormal fissuration. The gall-bladder was not entirely enclosed by liver-tissue, but a portion was exposed.

---

At a stated meeting held June 8, Drs. J. D. Steele and W. R. Butt presented a communication entitled "The Tests for Occult Blood in the Feces." He pointed out the value of these tests in the recognition of various conditions attended with the escape of even small amounts of blood into the gastrointestinal tract not appreciable macroscopically. In the application of the tests it is to be borne in mind that the presence of meat in the diet, the administration of beef-juice, injury from the employment of enemata, the existence of hemorrhoids, must be excluded as possible sources of the blood. The most available tests consist in the extraction of the feces first with ether and then with acetic acid and ether, and the addition of an ethereal extract of aloin in the one instance and of an alcoholic solution of guaiac in the other instance. In the presence of blood the addition of hydrogen dioxide will develop a red color under the conditions first named, and the addition of old oil of turpentine a bluish tinge under the conditions second named. The tests are exceedingly delicate. Drs. D. L. Edsall and C. A. Fife presented a communication entitled "The Influence of *X*-Ray on Metabolism in Gout." Led by the success attending the employment of the *x*-rays in the treatment of some cases of leukemia and the profound increase in metabolic activity exhibited under such conditions, they were led to employ the same agent in the treatment of two marked cases of gout. The result was that no apparent influence was exerted upon the clinical course of the disease and likewise none on the metabolic activity. Dr. D. L. Edsall presented a communication entitled "Milky Non-Fatty Effusion in Hodgkin's Disease." He reported the case of a child presenting multiple glandular enlargement, with the histological features of Hodgkin's disease. General dropsy developed and the fluid effused into the pleural cavity on one side was found to be milky. Physical and chemical examination of this fluid showed that it contained only a small amount of fat and led to the belief that the turbidity was due to globulins. Dr. W. E. Robertson exhibited the specimens from this case. The retroperitoneal and mediastinal glands were enlarged and they contained three types of giant-cells. The spleen was enlarged and contained numerous accumulations suggestive of abscesses. Dr. G. P. Muller exhibited a specimen of "Cystic Sarcoma of a Metatarsal Bone." The condition is a rare one and is important clinically from the fact that it is relatively non-malignant and accordingly requires less radical surgical treatment than otherwise. Dr. David Riesman presented "Specimens from a Case of Hemorrhagic Infiltration of the Kidneys in the Newborn." There had been no difficulty at birth, but on the third day suppression of urine set in and death took place amid convulsions on the fifth day. Both

kidneys and one lung were found infiltrated with blood. Dr. Riesman had noted like lesions in a few other cases. Similar conditions have been described by other observers and they have been attributed to traumatism resulting from pressure, torsion, and traction in the act of parturition, but Dr. Riesman was inclined to consider the affection a morbid entity, perhaps dependent upon an infective agent.

## Therapeutic Hints.

**Inspissated Cerumen.—**

℞ Sodii bicarb. ..... 1.00
Acidi carbolic ..... 0.60
Glycerin .....
Aquæ .....āā 15.00

Sig. Twenty drops instilled into the meatus, several times before syringing, to soften the wax.—*Medical Review of Reviews.*

**Acute Dysentery.**—R. J. Windle recommends the following combination:

No. 1.

℞ Chloral hydrat ..... gr. xx-xxx.
Liq. opii. sed. ..... ɱxx.
Aq. ad. ..... 5i.
Syrup. aurant ..... 5ii.

No. 2.

℞ Pulv. ipecac. ..... gr. xx-xxx.
Aq. chloroformi ..... 5i.
Mucilag. tragacanth. ..... q. s.

No. 1 draught is given, and usually takes effect in from ten to fifteen minutes. When the patient is just asleep he is sufficiently aroused to take No. 2. It must be shaken up in a phial and poured out just before being taken. In many cases the patient will, after this treatment, sleep from three to six hours, and wake without experiencing any inconvenience. In some cases the ipecacuanha does produce sickness in spite of the chloral draft, but in these the author has not been known it to come on in less than one and a half hours, and in no case did the vomit contain ipecacuanha, showing that it had already been absorbed—*Journal of the Royal Army Medical Corps.*

**Warts.—**

℞ Sulphur. sub. ..... 5v
Ac. acet. glac. ..... 5iiss.
Glycerin ..... 5ii.

M. Sig. Apply the paste to the warts on small pieces of linen or spread with a brush at night. Wash off the next morning. Repeat till the wart drops off.—*The Surgical Clinic.*

**Bubonic Plague.**—The following is recommended by Nascarenhas:

℞ Pot. iodid. ..... gr. clxxx.
Pot. chlorat. ..... gr. clxxx.

Put into a bottle and shake for about five minutes, then add three ounces of pure hydrochloric acid and keep in a cool place for ten days. Then throw away the mother liquor, weigh the crystals, and dissolve in twenty times their weight of water. Dose for plague patients, 15 to 40 minims four to six times a day. For ordinary fever, 10 to 20 minims four times a day, and as a preventive 5 to 15 minims once a day. Of 127 cases treated with this solution, 61 recovered. It must be remembered that the solution is depressant and heart stimulants must be added when needed.—*Indian Medical Record.*

**Cold in the Head.**—Ten grains of sodium salicylate are given every four hours for six or eight doses, and a grain of calomel at bedtime the first night after the onset of symptoms. Meat and meat soups should be abstained from. The following lotion is used to irrigate the nares:

℞ Acid salicyl. ..... gr. ii.
Acid boric. ..... gr. xx.
Thymol. ..... gr. ii.
Ol. eucalypt. ..... ɱv.
Spts. vini rect. ..... 5ii.
Glycerin ..... ɱxxx.
Aquæ dest. ad. ..... 5i

Ft. lotio. Sig. The lotion to be mixed with two or three parts of tepid water and used with a glass nasal douche.—*Medical Times and Hospital Gazette.*

**Tonic After Pulmonary Ailments.—**

℞ Tinct. strophanthi.....
Quin. hydrobrom. ..... gr.ii.
Acid hydrobrom. dil..... ɱx.
Syr. aurantii ..... 5ss.
Aq. chlorof. ad. ..... 5i.

Sig. To be taken three times a day.

℞ Tinct. strophanthi ..... ɱv.
Tinct. nucis. vomic. ..... ɱv.
Syr. aromat. ..... 5ss.
Aq. dest. ad..... 5ss.

Sig To be taken three times a day.—*Beasley.*

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 12, 1905:

| | Cases | Deaths |
|---|---|---|
| Measles | 178 | 9 |
| Diphtheria and Croup | 177 | 25 |
| Scarlet Fever | 37 | ..... |
| Smallpox | ..... | ..... |
| Chickenpox | 12 | ..... |
| Tuberculosis | 421 | 165 |
| Typhoid Fever | 254 | 26 |
| Cerebrospinal Meningitis | 26 | 19 |
| Typhus Fever | ..... | ..... |
| Yellow Fever | ..... | ..... |
| Cholera | ..... | ..... |
| Totals | 1105 | 244 |

**Some Symptoms of Cerebellar Tumors.**—J. Michell Clarke declares that affection of hearing often occurs in cases of cerebellar tumors because they exert pressure on the auditory tracts or nerves. It is either unilateral or is more marked on the side of the lesion. In some cases tinnitus aurium is associated with deafness. The writer, however, reports two cases in which absolute and complete deafness was accompanied by very distressing tinnitus aurium. It was on account of the deafness that advice was sought at first, for the deafness and tinnitus long preceded the pathognomonic symptoms of cerebellar tumor. Later, in one case, optic neuritis developed in one eye, and incoordination of movement showed itself in the other case. Until these symptoms appeared it would have been impossible to clinch the diagnosis. The writer points out the importance of bearing in mind the occurrence of deafness and tinnitus as occasional early signs of a cerebellar tumor. When a tumor grows in the corpora quadrigemina it may cause complete deafness. The average duration of all cerebellar tumors is two years. The cases here reported had a much longer duration, the first one being first seen by the writer in 1807, while death did not occur until 1904. The writer also refers to tremor as a symptom of cerebellar tumor, and reports a case in which this was a marked symptom. It resembled that of disseminate sclerosis.—*Friedel Medico-Chirurgical Journal.*

**Local Action of the Tuberculous Toxins.**—J. Auclair and P. Radiguer contend that the effect of tuberculosis is primarily a local one, the general effects being late and entirely secondary. When tuberculous cultures are injected under the skin of an animal there arises first an ulceration, then infection of the near, and later the deep lymphatic glands; if the injection was in the abdomen, infection follows of the omentum, of the liver, and the spleen, all local processes. The same takes place in the lungs, a local process that for long gives no marked symptoms. It is the same with the bones, and other forms of surgical tuberculosis: the patient's general condition is not at first affected, only after a considerable period are there general effects. We may go on to show the same facts with reference to the lungs, larynx, and other respiratory organs, whether the process be slow or rapid. The gravity of the case depends on the bacillus of Koch, acting by its toxins locally. Fibroid processes in phthisis should not be considered a form of healing; they go on not to repair, but to gradual destruction. The kidney may be the seat of this local poison; interstitial nephritis may result. As we progress in the knowledge of the tuberculous lesions the importance of the infection with its local intoxication increases. By its extension, the multiplication of its lesions, it goes on to destroy the organs of the body.—*La Bulletin Médical.*

### ASTHMA.*

By SAMUEL KOHN, M.D.,
NEW YORK.

ATTENDING PHYSICIAN, DEPARTMENT FOR DISEASES OF THE NOSE, THROAT AND EAR, GERMAN POLIKLINIK.

It requires a degree of hardihood to appear before you with a paper on a subject so trite and yet so full of problems as asthma, but I am emboldened to the undertaking, first, by the circumstance that I have been especially requested to do so by the president of the society, and, second, by the fact that in the medical periodical literature of the day we rarely see articles on this subject. The study of asthma is of engrossing interest for the reason that nearly our entire knowledge of its nature and course is based upon clinical observation; the views, therefore, of different writers and observers are widely at variance and frequently seem to be in direct conflict.

It has no distinctive pathology; the lesions which actually cause the disease have not as yet been discovered, nor has bacteriology thus far shed any light upon it. In severe cases the patient seems to be on the verge of dissolution in the asthmatic paroxysm, yet, grave as the condition is, all authorities agree that death is extremely infrequent; therefore, very few autopsies on asthmatic patients are on record. We know that asthma is a disease characterized by attacks of paroxysmal dyspnea, occurring at all periods of life, from earliest infancy to old age; sometimes, in persons who apparently, to all intents and purposes, are perfectly healthy, and again, in such patients as are suffering from the results of cranial injuries, from neurasthenia, respiratory, cardiac, renal, gastrointestinal, skin, or uterine disorders, or from the diseases of metabolism,—rheumatism, gout, and allied disorders. Males are more frequently affected than females, in the proportion of three to one, approximately. Hyde Salter's statistics show that more cases originate between the first and tenth year, than during any other equal period of life; he has seen the disease in infants of 14 to 28 days, respectively. At this early period of life we must take care not to confound cases of thymic asthma (Koppii)—erroneously termed asthma—because due to a compression of the trachea by an enlarged thymus gland, nor with the rare cases of congenital laryngeal stridor, due to hypertrophied, redundant, and relaxed mucous membrane at the laryngeal entrance.

The dyspnea of asthma is characteristic. It is both inspiratory and expiratory, the duration of inspiration compared to expiration being as one to four. From the beginning of the attack, the patient's energies are directed to prolonging the inspiratory act, with the object of getting more air into his lungs; but the more laborious his efforts, the more futile they become, until finally, carbonic acid intoxication may become so deep as to paralyze or anesthetize the nerve centers governing respiration, and the attack comes to an end. This labored breathing may be attended by loud wheezing, due to the secretion of the bronchial mucous membrane, which is audible at a distance from the patient, or there may be an absence of moist sounds, and puerile breathing without râles may be heard over the whole chest on auscultation.

Now, what is the direct cause of this paroxysm of exaggerated dyspnea? Bronchial spasm causing an obstruction to the ingress and egress of air was the explanation advanced by Trousseau and later by Biermer—brought about by the contraction of the circular muscular fibers of the bronchial tubes—Reisseisen having demonstrated the presence of muscular fibers in the bronchioles and their contractility by galvanism.

Wintrich claimed later that spasm of the diaphragm was the sole cause of the asthmatic paroxysm, instancing its rigid position during the attack, its depressed position in clonic contraction, and also the contraction of the large abdominal muscles to a board-like hardness, and supported his theory with most convincing arguments.

Weber in 1872 advanced the theory that paresis of the vasomotor nerves supplying the bronchial mucous membrane is the real cause of the narrowing of the bronchial caliber—the blood vessels being deprived of the nerve supply which maintains their contractility, become so dilated that the mucous membrane is swollen, tumefied, somewhat edematous, slightly coated with a seromucous discharge as a result, and that thus an obstruction is offered to the passage of air during both inspiration and expiration. To account for the contraction of the bronchioles, Leyden, in 1871, published his article attributing it to a local irritation from peculiar crystals which he discovered in the sputum and which he claimed produced an exudative bronchiolitis. These crystals, now termed Leyden's crystals, are sharply pointed, octahedral; they have also been called Charcot's crystals; later, authorities claimed to be able to find them in any bronchial secretion which was stagnant for a length of time, as the result of fermentation. Later came the spirals of Curschman to explain the bronchial spasm. These again were proven to be of no direct import, as they were shown to represent simply plugs of fibrin from the finer bronchi, expelled by the expired air, to which a spiral or corkscrew motion is imparted by the ciliated epithelium of the air passages.

The theories which to-day are most generally accepted in explanation of the direct anatomical cause of the asthmatic paroxysm, are the bronchospastic, combined with the vasomotor paretic,

* Read before the Metropolitan Medical Society, April 25, 1905

these two factors being associated with spasm of the diaphragm from irritation of the roots of the phrenic nerve; the true basis of these conditions being that the respiratory and vasomotor centres are simultaneously affected by the causes to which I shall allude later. An important question to be considered at this point is, is asthma a disease *per se*, or is it a symptom? Authorities favoring either view could be cited. In order to reach a conclusion, let us consider its nature and etiology.

Experience has proven that the disease occurs principally in persons of a neurotic temperament, the predisposition being frequently hereditary. That the tendency to asthma, or to the asthmatic temperament, is often inborn, is proven by the fact that in some families it affects successive generations, and that in such families several children may be simultaneously afflicted. It has been noted by some of the older clinicians (Pridham and Aitken) that asthmatics possess great energy and ambition; that those in humble life are often possessed of intellectual gifts beyond their station, and excel in any calling they may be pleased to follow. The disease is said to occur comparatively more frequently among the upper than the lower classes. Asthmatics being possessed of this neuropathic temperament, are overanxious to accomplish things. They are pushing, enterprising, they spend more nerve force in accomplishing things than those whose nervous equilibrium is not so disturbed. The asthmatic, therefore, frequently achieves success where others fail, but, as stated, at the cost of his health. It is this circumstance perhaps which explains the claim of Soltmann that asthma occurs more frequently among Jews than among Christians, comparatively.

This excitable, high pressure, neuropathic temperament which is more frequently hereditary than acquired, forms the basis for the predisposition to the disease, and in some cases is, so far as is discoverable, its main cause. Many writers, basing their views upon the comparatively slight causes that can induce a paroxysm of asthma in those predisposed, state that pure asthma is a neurosis, analogous to urticaria, hyperidrosis, etc., and that the entire nervous system in asthmatics is so affected as to be beyond the control of the patient, that the will power becomes almost entirely abolished when any cause for the attack appears. Such is the condition which exists when the first cause for the asthmatic paroxysm manifests itself. The causes producing the first outbreak of the disease are to be sought in the bronchi, the nose, the upper parts of the respiratory tract, the gastrointestinal canal, the sexual or reproductive organs, the skin, etc., and will be found in irritations of peripheral nerve endings of the vagus or other nerves connected with it, which, conveyed to the centers in the medulla, there cause circulatory changes which, reflexly, through the motor fibers of the vagus and the sympathetic nerves bring about spastic contraction of the bronchioles and congestion of their mucous membrane, resulting in the asthmatic attack. The *essential* cause of the disease, that which constitutes the individual an asthmatic, is probably some organic lesion of the nerve centers of the medulla, but this has not yet been demonstrated. In children, the pressure of bronchial glands on the terminal filaments of the vagus may have an important bearing on the causation of the disease. Many cases are on record in which repeated attacks of bronchitis in the young, an attack of measles or whooping-cough, have resulted in producing the first asthmatic paroxysm.

In 1871 Voltolini published eleven cases of asthma which he claimed to have cured or relieved by the removal of nasal polypi. This publication marked an epoch in the literature and led to the belief that finally the real cause of asthma had been discovered. This hope was soon shattered. Well-known writers in Germany, England, France, and America, basing their conclusions on the apparent analogy between asthma and hay fever and upon their prolonged success in the treatment of asthma directed to the nose, unqualifiedly endorsed Voltolini's views, going even further than he in their enthusiasm for the new method (Hack, Schmiegelow, Heymann, Lublinski, Greville MacDonald, Bosworth). Bosworth, in 1886, after long and painstaking observations, went further than any other writer, in claiming that almost every case of asthma is due to nasal disease or deformity, and hence, that virtually every case is curable by removing the polyps, sawing off exostoses, straightening septal deformities, or treating hypertrophies or sinusoidal disease by appropriate methods.

The success of the treatment of the nose in the relief of asthma was explained by pointing out the important secretory function of the healthy nasal mucous membrane, the enormous extent of its surface, the turbinates being considered as bodies of coiled mucous membrane—which, besides removing dust and other foreign particles that act as irritants upon the bronchi from the inspired air, impregnate it with moisture or watery vapor to the extent of sixteen to twenty ounces per day. Again, the difficulty in breathing experienced by those suffering from obstructive nasal disease, lent the nose great importance as an etiological factor; and the writers named, when they published their brilliant results in the cure of asthma by the abolition of pathological nasal reflexes, through operative procedure or local treatment, undoubtedly believed that they had at last solved the vexed question of the real causation of asthma.

Before long, came the revulsion, and we find that Böcker states that in 360 cases of nasal polypi he found only 9 cases of asthma; Hering found 7 asthmatics in 200 cases of nasal disease. In view of such statistics, it was not to be believed that the nose is the seat of the main cause of the disease. Other writers, again, presented statistics to show that in a majority of cases of asthma no nasal disease could be found. Francis made the surprising statement that the removal of nasal polypi or other obstructions frequently aggravates the disease by enlarging the caliber of the nares, thus permitting more irritants to reach the bronhci. In 402 cases of asthma Francis found the nose normal in 346. But he made the further claim that better results in the cure of asthma are achieved in treating the nose, in which *no organic lesions* are present, by using the galvano-cautery on that portion of the nasal mucous membrane covering the upper portion of the triangular fibrocartilage of the septum, on the ground that this is the most sensitive area of the organ; this area is termed by Brügelman one of the asthmogenic areas of the nose. By this method Francis claims to have cured 60 per cent. out of 600 cases; to have obtained marked relief in 27 per cent., and in only 5 per cent. to have had no improvement.

Such opposing views did not tend to strengthen the hope that the vexed questions of etiology and treatment had been solved; it was at about that

time that Morell Mackenzie was led to ask the question, somewhat humorously, as to what really constituted a healthy nose? And this question has not yet been answered. Replying to Mackenzie, Francis stated, given an asthmatic with an apparently healthy nose, galvano-cauterization in the asthmogenic area will effect a cure, and there seems to be some ground for the belief that this may, in some cases, be true. Lublinski in 500 cases of asthma found 143 with some pathological condition in the nose in which only 8 were cured of their asthma by nasal treatment alone and 4 were relieved. The writer has seen in clinics and in private practice, many hundreds of cases of nasal disease, including polyps, exostoses, hypertrophies, septal deformities, sinus disease, etc., and though he has made no statistics, he can assert with absolute certainly, that the occurrence of asthma concurrently with these diseases of the nose is infrequent—very infrequent—and this is probably the experience of every rhinologist of to-day.

On the other hand, cases of asthma will be found now and then, to be associated with nasal disease, the proper treatment of which undoubtedly will favorably affect the course of the asthma, but can only rarely cure it absolutely and permanently, for the reason that the basic cause lies in certain changes in the nerve centers governing respiration, and for the further reason that other causes may be present in the system besides the nasal disease. The clinical course of hay fever lends much color to the belief that the nose may be the starting point for asthma; we have, at the outset the protracted attacks of sneezing, associated with succulent swelling of the nasal mucous membrane occluding the nares; coryza, which in turn gives place to general bronchitis and finally to attacks of asthma; the nasal occlusion results in rarefaction of the air in the bronchi and alveoli, similar to a dry cupping,—and in this way, congestion of the entire respiratory tract is produced; this certainly presents a pathological picture resembling true asthma. Again in some persons, touching the sensitive areas of the septal mucous membrane with a probe, will produce an attack of bronchial spasm. These sensitive areas may be found in the mucous membrane of the entire respiratory tract, in the pharynx, larynx, and trachea, and even in the bronchi, and are termed asthmogenic areas. Bosse claims in all such cases to have traced the nerve connex between the trigeminus or other sensitive nerve, and the vagus. All these cases, depending upon nasal disease, have been classed under the generic head of nasal asthma.

Patients suffering from stomach disorders frequently show a marked predisposition to asthma (asthma dyspepticum), and appropriate treatment—lavage, etc., of the stomach—has resulted in marked amelioration of the disease. Many such cases, due to absence of free hydrochloric acid in the stomach, are to be found described in the literature (Murdoch, *Pittsb. Med. Jour.*, Jan. 12, 1901; Einhorn); the irritation of the gastric filaments of the pneumogastric is evidently the cause of the paroxysm. During pregnancy, paroxysms of asthma may occur, due to achylia gastrica or to hyperchlorhydria. On the other hand, cases are recorded in which asthmatic women remain free from attacks, during pregnancy.

It is sufficient to mention cardiac and renal asthma to indicate the connection between the heart or kidney disease, and the asthmatic paroxysms; the distinction must be made, however, between cardiac or renal dyspnea due to disturbances in the circulation simply, or to uremic intoxication, and essential asthma which is a disease *per se*. The dyspnea dependent on insufficiently compensated valvular disease, or through the poisoning of the blood from improper or insufficient functionlizing of the kidneys, is entirely separate and distinct from true asthma, occurring under these same conditions.

Among other causes which may induce asthma, are inflammatory ethmoidal disease, atelectasis of the lungs, repeated attacks of catarrhal pneumonia and mediastinal tumors. Pawinski (*Rev. de Med.*, No. III, 1899) describes a "blasen asthma" due to enlarged prostate in which the paroxysms could be terminated by catheterizing the bladder. Gout, rheumatism, obesity, and the other diseases of metabolism undoubtedly often lead to attacks of asthma. Cases are recorded in which attacks of gout alternated with paroxysms of asthma, the patient being free from the one when the other appeared. Patients suffering from eczema, psoriasis, and urticaria may have attacks of asthma alternating with the eruptions of these skin diseases, but just as is the case with nasal disease, only a small percentage of sufferers from these cutaneous disorders have asthma, and *vice versa*. The occurrence of these eruptions seems to be due to the same neurotic influences that are at work in the production of asthma. To the variety of this disease produced by the presence in the blood of irritants to the nerve centers directly, the name hemic asthma has been applied.

There remains to be mentioned asthma due to traumatisms of the skull, producing such changes in the cerebral circulation as to affect the respiratory center; neurasthenia, uterine and sexual causes, and finally toxic asthma, under which may be mentioned "*asthma saturninum*," described by Levy (*Oesterr. Zeitsch. für Heilkunde*, XVI, P. 6, 1890), occurring in chronic lead poisoning. Brügelmann (Wiesbaden, 1901), who has written copiously on this subject, sums up by saying that the sole and only way in which asthma can be produced is by irritations of the nerve centers, be they somatic or psychic, reflex or toxic.

The writer has gone to some length for the purpose of showing that although the views of causation especially as regards the nose, are very divergent—the fact which stands out distinctly, in all that has been written, is, that peripheral or central irritations, be they in the nose, throat, bronchi, skin, viscera, or in the circulatory media, or in the brain itself, in certain individuals of a neurotic temperament produce a characteristic, distressing, periodic dyspnea which is *sui generis;* it is unlike the dyspnea of destructive lung disease; it is entirely different from cardiac or uremic dyspnea; it is well defined and unmistakable in the suddenness of onset of the paroxysm, the seeming gravity of respiratory insufficiency that makes those about the patient fear that death is imminent, and in the more or less rapid return to a normal condition. It is the consensus of opinion, that this uniformity entitles asthma to be considered as a disease and not as a symptom. Scanes Spicer denominates pure asthma as the "original sin" or "the deep depravity of the nerve center;" and Colin Campbell has no doubt that a germ or a bacillus not yet discovered, is at bottom the cause of the disease, basing his view on the observation that the dyspnea continues to grow worse so long as the mucous membrane remains dry, and commences to relax as soon as expectoration of the secretion sets in.

Aprosexia nasalis, so named by Guye of Amster

dam, which is a rare variety of vertigo produced by intranasal lesions, is said by this writer to be sometimes associated with asthma.

*Exciting Causes of a Paroxysm.*—In cases of so-called pure or essential asthma, the paroxysm comes on without any apparent reason, usually towards morning, awakening the patient from a sound sleep. The most trivial causes are usually assigned therefor, as, for example, that the room was too dark; that it was not sufficiently ventilated; that the patient had changed his room from one part of the house to another; that the heat from the furnace had vitiated the atmosphere. Overindulgence in food or drink the preceding evening is frequently blamed; an indigestion due to indulgence in cheese, nuts, raisins, candy, malted liquors, salt or bickled meats, heavy wines or champagne. But even with this knowledge, asthmatics repeat these errors in diet time and again, showing that they are either forgetful or, what is more probable, that they have a very weak will power. Those predisposed may be stricken by an attack during the day from causes relating to the olfactory, respiratory, or psychic centers, for example, the odor of a drug store, of ipecac, violets, emanations from a cat, a horse, a rabbit, dog or duck; fog, smoke, or pollen may cause an attack in some persons; the dust of flour or meal in the air, or a strong wind blowing dust into the lungs will cause it in others; an attack of coughing or laughing unpremeditatedly, or physical exertion, all of which induce prolonged inspiration, and a slight overaccumulation of waste products in the blood may induce a paroxysm. Running, jumping, inordinate laughing, running up a flight of stairs, a severe attack of coughing, come under this head. Under psychic causes may be mentioned mental excitement, fright, rage, great joy, or profound mental preoccupation. Austin Flint the elder had an attack whenever he smelt feathers. Constipation is frequently the cause of an attack. Fear of an attack (*angst neurose*) plays a great rôle in keeping these patients in a condition of constant susceptibility to any cause which presents itself. Hyde Salter mentions a case in which the application of cold to the instep brought on an attack of asthma.

*Symptoms.*—As stated, the paroxysms occur periodically, either daily, weekly, monthly, or annually, or at irregular periods; in some patients asthmatic breathing in a mild form is constantly present, and becomes severe when any irritation presents itself; while in some, the attacks occur only at night; in others they may occur at any time of the day. In some patients the nocturnal attacks are preceded by premonitory signs; drowsiness, dragging in the limbs, joints, or testicles, pains in the back or loins, or there may be mental buoyancy and activity and cheerfulness; the presence of these forerunners has been considered by some writers as similar to the aura, and has led Burney Yeo to draw comparisons between the asthmatic paroxysm and the epileptic convulsion. The dyspnea or oppression in breathing which awakens a patient from a quiet sleep and which rapidly gains in intensity because of the absolute lack of will power in the patient to control it, causes the patient to jump out of bed and to assume the position in which he finds himself best able to conduct his struggles for air; most patients sit down near a table upon which they plant their elbows, holding the head with both hands firmly; breathing is most laborious and is attended by loud wheezing; inspiration, which is attended by intense muscular exertion on the part of the intrinsic and extrinsic respiratory muscles, grows shorter and shorter as the attack progresses; the muscles passing from the head to the shoulder, clavicles, and ribs, are tonically contracted and almost entirely motionless; the muscles attached to the lower ribs show only limited movement; the diaphragm seems to be immovable; the abdomen distended and its broad muscles tense and board-like. The attempts of the patient to get air into his lungs are attended by the most meager results; his face becomes pale, perspiration breaks out all over his body, his mouth opens wide with each inspiration; ofttimes in the coldest winter nights he rushes to the open window and thrusts his head out to get more air. The face becomes livid, the eyes stand out congested, the patient can talk only in monosyllables, and is afraid to undertake the slightest muscular exertion; and the condition is one that arouses the anxiety even of the physician. The attacks may continue to grow worse until death seems imminent from carbonic acid intoxication, but this very condition blunts the nerve centers and ends the attack. It may, however, become so severe that consciousness becomes lost; tetanic spasms, opisthotonos and facial twitchings may be present; or, a slight cough may set in, at first hacking and very dry, but later attended by the expectoration of small pearl-like pellets of mucus, and this marks the starting point for the amelioration of the paroxysm, which may last from one-half to three or four hours. The expectoration may be jelly-like, transparent, or may be streaked with blood. Sometimes a true hemorrahge from the upper air passages or even hemoptysis may take place. Some patients stand up during the paroxysm, finding this position the only one they can endure. Hyde Salter relates the case of a man who for two days and nights stood immovable in one position.

Naturally, such attacks are attended by insufficient aeration of the blood, the heart's action becomes markedly interfered with, at times slowed and again accelerated, but always weakened. Passive congestion of the viscera sets in, and symptoms attributable to this, anorexia, headache, flatulence, highly concentrated urine, ensue; in some cases incontinence of urine and feces may take place.

In some patients, as the result of treatment or a change of climate, the attacks may become less frequent or may cease altogether; in others the disease continues to harass the patient until he becomes prematurely aged, or some intercurrent illness puts an end to his sufferings.

*Anatomical Changes.*—The anatomical changes in the lungs, which are responsible for this superlative respiratory difficulty, may be summed up in the words "*lungen blähung*," as the German writers have termed it; in other words, dilatation of the alveoli of the lungs. During the attack this dilatation grows more marked, the more strenuous the patient's efforts to force air into the lungs become; for the reason that the bronchioles being spastically contracted, very little air can get into the alveoli; and what air is therein contained becomes rarefied because the forced inspiratory act causes still further alveolar dilatation. The chest in asthmatics consequently becomes barrel-shaped from these oft-repeated attacks of labored respiration and lung dilatation. The alveolar walls in time lose their elasticity from the repeated strain upon their elastic fibers, and well marked emphysema may follow; when this is the case the asthma moderates in severity and may leave the patient altogether.

Expansion of the lungs, it has been claimed, is inconsistent with bronchial obstruction. This is perfectly true when the pulmonary alveoli have lost their elasticity completely; so long as this is not the case, the reciprocal effect of the atmospheric pressure, the forced attempts at inspiration, and the spasms of the muscles of the bronchioles is to produce rarefaction in the residual air of the alveoli by narrowing of the bronchioles.

With these changes in the lungs and as a result thereof, we find the liver depressed to quite a considerable extent, sometimes three fingers below the free border of the ribs. Sihle of St. Petersburg calls attention to this depressed condition of the liver as one of the characteristic pathological conditions in asthma. In addition we have a simple hyperplastic or fibrinous bronchitis, although pure or essential asthma may exist without the slightest sign of bronchitis, either as a concomitant or a sequela; in this case, the asthma is simply the manifestation of a highly deranged functionalizing of the respiratory center. These changes in the lungs, while they are regarded as part and parcel of the pathology of asthma, are rather the result than the cause of the disease. The writer has been able to find the record of only three autopsies on asthmatics, made respectively by Schmidt, A. Frankel and B. Levy. None of these investigators found anything characteristic on autopsy. Thus far no change in the nerve centers has been discovered to which the disease can be positively attributed; we are consequently driven to the hypothesis that there must be a molecular change in the nervous centers or a periodic disturbance in their vascular supply, and that, as stated, the asthmatic attack, like that of urticaria, migraine, or epilepsy, is the culmination of a series of irritations transmitted to the nerve centers, which finally result in the explosion which, in this case, is the asthmatic paroxysm.

Sihle of Odessa (*Russ. Archives of Pathology*, etc., Dec. 31, 1902) adds a fourth to the three etiological factors in asthma; these are, first, spasm; second, specific catarrh; third, congestion, and fourth, a general vasomotor insufficiency as exhibited in the lower blood pressure; the venous stasis in the liver is not due to a weakened heart action, but to lowered blood pressure in the arteries. With Gärtner's tonometer, this lowered blood pressure has been demonstrated by Sihle.

There are changes in all the other organs of the body depending upon the frequent disturbances of respiration and circulation, in the heart, the kidneys, skin, hair, nails, etc., which it is not the province of the writer to describe in this paper.

*Diagnosis.*—The diagnosis of essential asthma is not difficult; a consideration of the family history, of the symptoms and course, and a careful examination of the patient will not leave much room for doubt. And still, a thorough examination not only of the thorax, but of the entire body should be made for the purpose of ascertaining, if possible, the cause of the disease, and for the further purpose of excluding thoracic growths, aneurysm, or glandular enlargements. A laryngoscopic examination is necessary to exclude a posticus paralysis which may at times give rise to dyspnea simulating asthma, but which is peculiar in that the inspiratory dyspnea predominates over the expiratory. The nasopharynx should be examined for adenoids; the nose and pharynx should be thoroughly explored and probed for the purpose of finding asthmogenic areas. Due attention should be paid to the heart, stomach, and kidneys so that, if needful, treatment may be directed to these organs. Hysterical patients sometimes develop a dyspnea much resembling asthma, which is readily relieved by the ordinary appropriate treatment for this condition. The uterus and adnexa and the sexual organs should be thoroughly looked after. Sigismund Goldschmidt (München, 1898) draws a distinction between emphysema and asthma, claiming that in the dyspnea of emphysema marked cyanosis is present, while in asthma it is absent. Then there are those rare cases of some unusual peripheral irritation keeping up the asthmatic paroxysm—*e.g.* St. Clair Thompson reports a case in which stretching of the sphincter ani brought about a cure in an obstinate case, while McKay McDonald reports two cases in children about the age of ten years in whom a forcible digital examination for adenoids brought about a complete cessation of the attacks.

All of which shows the necessity for a careful, complete, thorough, and painstaking examination of every part of the body, before making a diagnosis of pure, essential asthma, and before deciding upon the treatment which is appropriate to the individual case. Montcarge claims that increased knee jerks are present in asthmatics. And finally we must exclude thymic and thyroid hypertrophy, spasm of the vocal chords, adenoids, and collapse of the lungs from rachitic conditions of the chest.

*Physical Signs.*—Between attacks, the only signs to be observed are, on inspection, the enlarged barrel-shaped chest in chronic asthmatics, which in those only recently affected is absent. On auscultation, there is a soft respiratory murmur all over the chest, and here and there slight râles may be found, showing the presence of bronchitis; although, as stated, this may also be absent. On percussion, tympanitic resonance all over the chest. During the attacks the chest shows much diminished respiratory movement, especially in its lower parts; all the muscles of respiration are tensely contracted; large and small mucous râles, sonorous and sibilant, are to be heard over every part of both lungs, causing a sound similar to that made by a music box. In the rare cases of pure, essential asthma, there may be puerile breathing over both lungs, and no moist sound whatever may be heard. The area of precordial dullness is diminished because of the expanded lung tissue encroaching upon the heart area. The right heart is hypertrophied, and sometimes dilated from engorgement. The diagnosis of bronchial glands in children may sometimes be made from a venous hum heard in the descending vena cava or in the innominate veins, produced by pressure on the veins, and interference with the circulation.

*Prognosis.*—Although the prognosis as regards life is good, the same cannot be claimed as to cure, unless the patient is so circumstanced as to be able to follow every recommendation of his physician. While there is no immediate danger to life, the disease, in a severe form, is a dire calamity to the individual, interfering with his progress, material and mental, in every way. Death during the paroxysm is extremely rare, and many writers deny that it ever occurs. The chief danger, unless the disease is checked by treatment, is the establishment of chronic bronchitis and emphysema, with the long train of pathological changes in the other organs of the body which these diseases involve. If the disease remains unrelieved for a long time the disturbances in the circulation, the strain on the mind and body, so weaken the patient that he is liable to fall a victim to some intercurrent disorder.

Pure uncomplicated essential asthma occurring in the young, is amenable to treatment, and the prognosis is good—that is, in children or young adults who show absolutely no signs of disease of any other organ; in fact, at puberty the disease in many cases ceases spontaneously.

In those whom the disease attacks after the thirtieth years or who suffer from bronchitis either simple or fibrinous, cardiac or renal disease, the prognosis as to complete recovery is unfavorable. And still, cases are reported in which the paroxysms remained absent for a long time in adults, only to return upon some slight irritation; and cases are recorded in which recovery occurred spontaneously.

*Treatment.*—The physician who would successfully treat asthma, must thoroughly understand the disease and its causation, and should be fairly well versed in all the specialties. He should understand laryngology, gynecology, neurology, dermatology, and, besides, he should be a good general practitioner. The treatment has for many years been along lines of such parallelism, and has been of so little efficacy in many cases, that asthma quacks the world over have thrived like the green bay tree. Dr. George Avellis (*Munch. med. Woch.*, October 25, 1904), in an article on the quack treatment of asthma, has taken pains to expose the methods of all charlatans, classifying their treatment as follows: First, by stramonium and allied drugs; second, by the compounds of iodine carefully disguised; third, by weak solutions of atropine; fourth, the periplocin treatment, which had a great vogue in Europe, and which is a combination of pyridin; fifth, inhalation of various sedatives and narcotics, including opium, camphor, ether, and chloroform; sixth, ordinary cathartics, sudorifics, diuretics, etc. He gives a long and detailed account of the Buffalo treatment, showing it to consist in the administration of turpentine emulsion, iodide of potassium, iron, cinchonidia, sulphur, opium, and ammonia in varying doses, according to the requirements of each individual case, which is ascertained through correspondence. The Tucker treatment, which gained a great vogue here and in England, has for its basis atropine used in spray, and nitrite of sodium, internally. Dr. Cholewa's treatment, apnol, consists of iodide of sodium, spirits of peppermint, pyridin, in solution in a spray.

We may divide the regular methods of treatment in use, at present, roughly into the following classes: (1) climatic; (2) hygienic; (3) symptomatic; (4) gymnastic; (5) psychic; (6) hydrotherapeutic; (7) medicinal; (8) operative; (9) institutional.

It has been the experience of physicians for years, that as a rule a high altitude relieves asthmatic patients of their paroxysms and of their disease, because of the rarefied air of the higher regions; and there is no doubt that on the high plateaus of New Mexico and Colorado these patients can live comfortably. But such is not absolutely the rule. Some patients, a small minority it is true, seem to get the most relief from the moist air prevailing at the seashore. Again, removal from the city to the adjacent suburbs where the air is not contaminated, will serve to give some patients the desired relief, and, on the other hand, as Salter has pointed out, asthmatics who live in the country sometimes get relief in the crowded city, and he instances a number of cases in which asthmatic patients from the rural regions obtained the greatest relief from a sojourn in London. An ocean trip has been known entirely to suspend paroxysms in some cases, and the value of a sojourn in one of the American or European mountain resorts is undoubted.

The hygienic treatment consists in seeing to it that the functions of the skin and excretory organs are regularly performed; in regulating the metabolic functions; in modifying the diet according to indications; forbidding overindulgence in food and drink, especially at night, and in interdicting all rich and fancy dishes and indigestible food. Malted liquors, heavy wines, and champagne should be strictly forbidden. Light alkaline mineral waters like those of Saratoga, seltzer, vichy, or Ems, should be used in moderation to keep the renal functions active. The baths of Saratoga or the Virginia Hot Springs, or in Europe those of Kissingen and of Marienbad, are to be recommended.

Under symptomatic treatment I refer to meeting the indications in each individual case, as, for example, in a patient with rheumatic symptoms, we should use the salicylates; in the gouty, colchicum; in the anemic, iron, arsenic, the glycoephosphates, etc.; in those of a marked nervous or hysterical disposition, valerian or the valerianates. Indications pointing to uterine, cardiac, renal, traumatic, or other causes should be treated accordingly.

The gymnastic and respiratory, and also the pneumatic cabinet treatment have found many advocates in Germany; as also the treatment by compressed air, as advocated by Waldenburg many years ago. This treatment by the pneumatic cabinet or compressed air is best adapted to cases of bronchial asthma in which some lung dilatation has already taken place. The main object that is sought to be achieved thereby is to prolong expiration, as by this means it is thought the alveoli become contracted and regain their elasticity. The forms of exercise vary, from simple calisthenics systematically employed, to walking long distances in the fresh air, and to keep breathing exercises in a chair especially constructed for the purpose and called the "asthma chair." One writer advises that patients be treated by exercises in breathing, which consist in counting slowly during each expiration; at first count up to five with each expiration, for about five minutes morning and evening. The next day count six, the following day seven, and so on until the patient can count up to twenty with each expiration. These exercises should not be overdone; finally, ten minutes morning and evening should be devoted to the purpose. Other methods have been described for prolonging the expiratory act, as, for example, breathing in expiration, with the lips so drawn together as to leave only a small opening

Dr. Benedetto di Luca (*Riforma Med.*, Dec. 6, 7, 9, 10 and 11, 1901), basing the utility of his treatment upon the theory that the paroxysm of asthma is due to a temporary state of irritability of the bulbar centers, particularly the vasomotor center supplying the bronchial muscles, recommends a measure for the purpose of depressing this irritability—stimulation of the nerve endings in the labyrinth, by means of vibrations of the body transmitted through the endolymph to the nerve endings of the acoustic nerve, the effect of which is to produce a vertigo similar to Menière's disease. To this end rapid rotary movements of the head or of the whole body should be made, until the patient becomes dizzy and nauseated; this is attended usually by perspiration, pallor, a rapid weak pulse; the author claims that a few minutes spent in these exercises will avert the paroxysm of asthma. I have had no experience with it.

Brügelmann lays much stress on the value of what he calls "education asthmatique," that is, in enlightening the patient upon the nature of his disease, and to teach him that by an effort of the will, asthma can be considerably ameliorated, and to

show the patient the necessity of leading a perfectly well regulated life: the importance of proper diet, sufficient sleep, of out-door exercise, principally walking long distances or horseback riding, breathing exercises with inspirations as deep as possible; keeping the functions of the skin and bowels regulated. He claims that by these methods alone, employed in sanitaria, the condition of asthmatic patients is very much improved without the use of any drugs. He strives further, by psychic methods, to strengthen the will of the patient by means of hypnotism and through suggestion, claiming to have achieved most excellent results in his own sanatorium in cases of pure nervous asthma by these means, without the use of drugs or any other means whatsoever. There can be no question but what autosuggestion plays a most important rôle in the cure of the disease, as it does in its production.

Hydrotherapy is of undoubted value in the treatment of selected cases, especially those of a purely neurotic character without bronchitis; but this method of treatment should be used with great care, because of the sensitive peripheral nerves of these patients and their great reflex irritability. The lukewarm shower daily is recommended, followed by friction with warm towels; douching of the nape of the neck with cool water; where patients cannot stand the shower the lukewarm pack for three or four hours at a time every day, may be tried. Massage of the chest, especially of its lower part, in the region of the attachment of the diaphragm, is sometimes productive of the very best results.

Under medicinal treatment we should distinguish between the palliative and the curative, the former being directed simply to the treatment of the attack and of the cough, the latter being made use of during the intervals between attacks. For the attack, the narcotics and analgesics—opium, morphine, chloral, chloralamid, bromide, and phenacetin may be given; morphine is given hypodermically during very severe attacks; but the administration of morphine or opiates should be a last resort, because worse even than asthma is the morphine-habit combined with it, which is rapidly acquired by these patients. The same is true of all other narcotics. Touching the pharynx with a mild solution of ammonia has been recommended for cutting short the asthmatic paroxysm, and, in some cases, is of value. A hypodermic of 1-150 of a grain of atropine is sometimes of value. The inhalation of a few drops of ether or chloroform sometimes causes an attack to subside, but frequently the relief is only temporary; and, finally, burning of the well-known stramonium and saltpeter powder, producing a dense smoke, is a specific in many cases for the attack; bibulous paper saturated with saltpeter which is allowed to burn slowly, producing a strong smoke, also will produce relief in some cases; but the smoking habit grows on these patients to such an extent that if possible we should discourage it and try to make use of other methods. Nitrite of sodium, in doses of two or three grains hourly, has been used with good effect, as also the inhalation of a few drops of nitrite of amyl. In some cases the inhalation of pure oxygen gas has proved very beneficial.

The treatment by drugs during the interval varies according to the individual case and according to its etiology; but, generally speaking, it seems to me that in the vast majority of cases the preparations of iodine have the most supporters, and in my practice the best success that I have achieved has been by the use of iodide of potassium. The dose in the beginning of the treatment should be very small—about one grain given in milk three times a day, and should be gradually increased, noting carefully whether the patient bears the drug well. If no symptoms of iodism and no derangement of the stomach ensues, the dose should be increased daily until the patient takes from twenty-five to thirty grains a day. It has been my experience in cases of pure asthma or bronchial asthma that by this means the number and the severity of the attacks are markedly diminished, and that finally the patients remain entirely free from attacks. As to the physiological action of iodine in these cases, time will not permit me to go into the question; suffice it to say that it stimulates gland secretion and lowers arterial pressure.

Frese (*Munch. med. Wochenschr.*, Dec. 14, 1898) praises iodipin in doses of one to three drachms three times a day. The iodide of sodium, or iodide of strontium may be tried where iodide of potassium is not well borne. Since the days of Trousseau, atropine has had innumerable advocates as a remedy for asthma. Dr. G. Campanella (*Gazzetta degli Ospedali*), June 22, 1902, on the ground that atropine diminishes reflex excitability, and reduces spasm, and secretion, recommends that this drug be given in increasing doses during the whole course of treatment, and claims the most excellent results. The experiments of Rossbach show that atropine, by inhibiting the secretory function of the bronchial glands and diminishing the reflex irritability of the vagus, exercises a marked curative effect; he gives atropine constantly during the disease, and even during the paroxysms, giving as much as one-eighth to one-sixth grain during the twenty-four hours.

The other drugs recommended in the treatment are arsenic given in gradually increasing doses, nitroglycerin, quinine, belladonna, iron, strychnine, and the other tonics.

For the cough, in place of narcotics, tincture of quebracho and tincture of grindelia robusta are recommended by Penzoldt; creosote and its allied preparations are sometimes of value. A prescription very much used for the cough in asthma is the tincture of lobelia combined with heroin, ammonium muriate, or the compound spirit of ether.

Glascow, having found on laryngoscopic examination during the attacks, marked anemia of the larynx and trachea, advises that the nitrites be given in large doses. Bullowa and Kaplan (*Med. News*, Oct. 22, 1903) describe the favorable effect of adrenalin administered hypodermically and by the mouth during the asthmatic attacks, upon patients in the Montefiore Home. They explain the rapid subsidence of the asthmatic paroxysm after the administration of adrenalin upon the ground that the blood vessels of the bronchi are in an angioparetic condition and that adrenalin acts by contracting the blood vessels and by restoring the caliber of the bronchi and their normal tone: they claim that from three to six minims of a 1 to 1,000 solution, either by the mouth or hypodermically, cut short a paroxysm in from three to six minutes, but admit that the attacks recurred at the regular time; hence adrenalin can be regarded only as a palliative measure. This treatment has been described before by Cohen of Philadelphia.

Various other organic extracts, like extracts of the thymus gland or of the thyroid in small doses, have been recommended in the treatment of asthma, and in appropriate cases are undoubtedly

of value. The local treatment of the trachea by a solution of menthol in solution, by instillation through the larynx has been recommended by Abrams.

From all that has been stated as regards treatment it will be understood why the operative treatment of the nose for the cure of asthma cannot possibly be of such widespread utility as its supporters originally claimed, although Francis, Bosworth, Schmiegelow, and Heymann claim to have cured the majority of their asthmas by nasal operation; it seems to me, in view of the prolific literature on the treatment by other methods, and in view of the neurotic nature of the disease that the claims of these authorities are somewhat exaggerated, and that a permanent cure of old cases is scarcely possible by treatment directed solely to the nose. There must be treatment by internal medication directed to the underlying cause, which, as has been stated, is in the brain, in the respiratory and vasomotor centers. In recent cases it is possible that treatment of the nose either by spray with liquid, or oily solution, or by galvanocauterization of the asthmogenic areas in the nose may result in cure, but when the disease has existed for some years, I cannot believe that this treatment alone will succeed. Every asthmatic patient should have his nose and throat thoroughly explored and cocainized, to note the effect upon his breathing, for diagnostic purposes; obstructing growths or exostoses should be removed, the nares should be made patent, purulent nasopharyngeal catarrh or ozena should receive appropriate and energetic treatment daily; in the nose which seems healthy, asthmogenic areas should be looked for with a probe, and if found should be treated carefully either by cauterization with chromic or trichloracetic acid, or galvano-cautery, lightly applied. It must be borne in mind that the asthmatic is such not because of some abnormality in his nose, bronchi, or in some other organ, but because, at bottom, there is a derangement of his entire nervous system and an irritable condition of his nerve centers with explosions in the domain of the vagus nerve.

We come now to the institutional treatment, which in Germany has many advocates; it is claimed that in a sanatorium for asthma, equipped with all the necessary aids to diagnosis and treatment, such as baths, pneumatic cabinets, compressed air apparatus, gymnastic and electric appliances and all other necessary instruments of precision, the best results can be achieved, especially, when to all of these means is added the constant supervision of physicians who thoroughly understand the disease and its causation. The moral or psychic effect upon an asthmatic on entering such a sanatorium with its iron-clad rules and regulations and its systematized treatment is excellent; the knowledge that he is under the care of physicians, expert in the treatment of his disease, is, in itself, apt to have a very salutary effect. In this way autosuggestion plays a great rôle in relieving the patient of his sufferings; and if there is any recommendation that I would make, as a result of my studies on the subject, it is that just as we have sanatoria for nervous diseases or diseases of women, there should be such an institution created for the treatment of this most obstinate and baffling disease.

13 East Seventy-fifth Street.

**Cocaine Addiction** is very prevalent among the Southern negroes, according to the Atlanta *Constitution*. The drug is taken usually in the form of snuff.

## FREEDOM FROM URIC ACID, AND HOW TO OBTAIN IT.

By ALEXANDER HAIG M.A., M.D., Oxon., F.R.C.P., London

The title of this paper does not, of course, mean that absolute freedom from uric acid can be secured, for this is impossible. Roughly speaking, everyone forms day by day about one grain of uric acid for every twelve pounds of body weight, this being a necessity of life. The freedom of which I speak is comparative, and may be obtained by excreting this quantity daily and regularly so that none of it accumulates in the system, and by cutting off all uric acid from external sources, so that there may be none to collect in various organs, and thus form a focus of retention both for the uric acid introduced and for that formed in the body. I propose in this paper to consider how this freedom, one of the most vital of our necessitites, may be obtained.

The problems concerned in the exclusion of extraneous uric acid I have treated at length elsewhere, and I shall therefore, confine myself here to those points connected with the daily and hourly excretion and elimination from the body of the urine acid formed within it.

A man of 140 pounds in the middle period of life will form, let us say, each day about 12 grains of uric acid. The problem to be considered is how to secure the daily excretion of this amount beyond the possibility of accumulation.

The physiology to be dealt with is briefly this: Uric acid is a substance soluble in alkalies; the solubility being somewhat increased by heat; it is insoluble in acids, the insolubility being somewhat increased by cold. The blood is practically an alkaline solution, but the ratio of alkali fluctuates; is is higher in certain hours of the day and lower in certain hours of the night, higher in certain conditions of nourishment and lower in others, higher (generally speaking) in debility and lower in high nutrition and in fever. The alkalinity is increased by heat and diminished by cold, for heat increases the elimination of acids from the body in perspiration, and cold diminishes it.

Cold and heat have thus a double action on the solubility of uric acid; a direct influence and an indirect one, through their effects on the alkalinity of the blood.

In the acidity of the urine we have a more or less exact indication of the alkalinity of the blood, for the more acid the urine the less alkaline the blood, and *vice versa*.

Practically, all conditions diminishing the alkalinity of the blood, and all substances (*e.g.* the metals), forming insoluble compounds with uric acid, cause its retention and lead to accumulation in the body.

In this paper, however, I am chiefly concerned with physiological conditions, the action of which is constant, and shall not devote much space to metals and other substances where the action is more or less temporary and accidental.

The chief physiological conditions diminishing the alkalinity of the blood are: (1) High nutrition, for a large metabolism of nitrogenous compounds means a coincident formation of acid substances corresponding with a large formation of urea; hence the gouty man is often the well-nourished man with good digestive power. (2) Cold, as from life in a cold climate, a cold house, sedentary occupation, or deficient clothing. Therefore, gout is a disease of the cold months of the year and its pathological antithesis, mental depression, is found in the warm months, and especially in the early warm months. Hence, "May is the month of suicides and murders,"

as a result of the circulation of the uric acid which was retained and accumulated in the previous cold weather, when gout prevailed from November to February.

Spring depression, anemia, lethargy, and debility are accordingly the consequences of the resolution and clearing out, or (to use a homely illustration), of the "spring cleaning" of uric acid retained in the preceding. Obviously, if the miseries of this spring cleaning are to be evaded, we must have no retention in the cold season, and my object in this paper is to discuss this question and consider the best methods of preventing, as completely as may be, all retention.

I write specially for those persons who have completed the first stage and have avoided all unnecessary ingestion of uric acid. These have only to deal with the uric acid of formation and provided this is not retained, they have practically the utmost freedom possible from uric acid and its ill effects. But people whose diet is uric-acid-free and those who live in the ordinary way will alike have less in their blood in May if there has not been any retention in the previous November, though it is much harder for those who swallow uric acid to avoid winter retention since their food is itself a cause, uric acid being a precipitant of uric acid and every focus of accumulation acting as a center of attraction to each particle of the same substance which is brought past it in the blood. And not only so, but each accumulation previously formed will increase as opportunity offers, so that persons who introduce uric acid have a much harder task to prevent accumulation than those who do not, and those who have already accumulations in the body will accumulate further quantities much more readily than people who have taken the trouble to clear out previous accretions.

As high nutrition produces low alkalinity of the blood, one simple way out of this difficulty is to underfeed, to take the smallest possible amount of food, and to secure thus a diminished formation of acids in the body and increased alkalinity of the blood. This is, no doubt, under certain conditions a useful method of dissolving accumulated uric acid, but it is nevertheless a dangerous plan and one not to be continued beyond quite a short period, or it leads to difficulties frequently much greater than those created by the cause it seeks to remove.

In the old textbooks of physiology from which I had to learn when I was a student a quarter of a century ago, it was stated that a vigorous and active adult would produce each day from 3 to 3½ grains of urea for every pound of body weight. Now, 3 grains of urea is produced from 9 grains of albumin. My rule (to which I have always held) is that to obtain sufficient food an adult must take the body weight in pounds and multiply by 9 to get the grains of albumin that he should consume daily. This produces somewhere about three grains of urea per pound, and if he is very active and has a keen appetite, he may take a little more than this from time to time when exercise is hard and appetite more than usually good. I have never seen any reason to alter this rule, but have, on the contrary, seen many reasons for relying upon it; both in myself and in hundreds of others I have carefully tested from time to time the possibility of living on less food, and have found that it is often dangerous to attempt to do so.

It has lately been asserted by various writers and experimenters that we eat too much food, and that it is possible to live on considerably less than the old physiological standard, but I can only say that I myself have never come across any conclusive evidence that this is the case. Professor Chittenden in his recent book, "Physiological Economy in Nutrition," points out that a number of men at various times of life and under varying conditions of activity, have been able to live and do good work on quantities of albumin below the German standard. But those who will take the trouble to look into this matter, will see that the quantities he mentions are but little below my standard above given, and in so far as they come short of it I believe (if continued for a sufficient length of time) they would lead to difficulty and even to danger, though, because the quantities were only fractionally below those I have used, these bad results might be imperceptible until they had been watched for periods of from eighteen months to two years. Mr. Horace Fletcher in a recent edition of his book, "The New Glutton and Epicure," (p. 278) cites me as a convert to his belief that if people chewed carefully they could live on less food; but I have never altered the opinion already expressed in the last edition of my little book on "Diet and Food," that, though it is undoubtedly important to eat slowly and to chew carefully, I see no evidence whatever that the exercise of even the greatest care in these matters will enable anyone to live on less albumin than that mentioned in the above rule. When I saw Mr. Fletcher some years ago, he acknowledged that his temperature was always subnormal, and I saw for myself that his blood color was defective and circulation slow, nor have I reason to think he is in any better condition to-day. I must express my decided opinion that those who have constant subnormal temperature, slow circulation, and a deficient quality and color of the blood, are always in a condition of possible danger, and in a position which I have always done my best to guard against personally, and for all who have trusted me with the direction of their diet. It is true that people thus circumstanced may, for some months at least, be capable of considerable exertion; they often feel lighter and better for some little loss of superfluous fat, and when underfeeding they, of course, swallow less uric acid and may indirectly derive some benefit in this way. But, if underfeeding is persevered with and, as I suggest, a gradual increase in the defects of circulation, blood color, and temperature follows, there will eventually come a time when they are within measurable distance of debility and collapse. And long before that they will have been to a very considerable extent in danger of attacks from the various microbes which are always seeking for the debilitated and undernourished on whom they may settle and flourish. Among such microbes I may mention those of boils and carbuncles, that of diphtheria, and (more important still because more widely spread), that of tuberculosis. All or any of these fastening upon an undernourished individual with subnormal temperature, defective circulation, and deficient blood color will readily obtain an entrance and may flourish at his expense; and it is germane to the matter to point out in passing that the only treatment of tuberculosis considered of any real use to-day is that of fresh air combined with a double allowance of food.

It is not necessary to underfeed because the ingestion of uric acid is discontinued. The natural amount, or double the natural amount of food (albumin), may be secured on uric-acid-free lines, but it should be remembered that if double food is taken a double excretion of acid in the urine and a correspondingly diminished alkalinity of the blood must be expected, and then very great precautions become necessary in other ways to prevent retention and accumulation of the uric acid of formation. With urea thus double, there will be also (we must remember) a double formation of uric acid, so that if a man on ordinary food forms 12 grains a day, on the above treatment he will form 24, and, while adding no uric

acid from outside sources, will still, from his increased formation and increased tendency to retention be in considerable danger of storing and accumulating some of this substance in the skin and tissues.

It is not denied that if such a course leads to the destruction of the microbe and consequent escape from tuberculosis, a patient may well put up with the lesser evil of some accumulated uric acid, but it is certainly no uncommon circumstance for those who have undergone this treatment for tuberculosis to suffer afterwards from a temporary excess of uric acid in the blood, and from its results.

The conclusion is, I think, that it is an error to take too much food except as a temporary remedy for serious disease, and that it is wrong to take too little food because we are thus exposed to the risks of debility and the wandering microbe. The right course is to secure just that quantity of nourishment which will keep the temperature normal, the circulation normal, and the blood color at the highest attainable level, and such a useful and natural condition may then be expected as will ensure the daily excretion and final riddance of all the uric acid of necessity formed in relation to the amount of albumin swallowed and the amount of urea thus produced.

Having thus settled the quantity of food required, we may notice shortly the other conditions necessary to be observed in order to pass out day by day all the uric acid formed in the body. These may be briefly stated: We must live warmly. No doubt man in his natural condition is fitted for a life in the warmer regions of the earth where nuts and fruits, his natural foods, grow in profusion, and if he has wandered away into the cooler regions where these foods grow with greater difficulty, he has always done so at his own peril. In this climate, therefore, it is necessary to clothe very warmly and to live in warm houses during a considerable portion of the year. It is also necessary to live a fairly active life so as to get rid of a certain quantity of the acid products of combustion through the excretions from the skin. A laboring man, from the conditions of his exertion has summer all the year round; and the sedentary suffer far more from climatic cold than those who live in circumstances which require natural efforts.

It may be of assistance if I mention the practices which have commended themselves to me and which I myself follow with regard to these matters, commenting briefly on each point, and giving my reasons for selecting the course I have chosen and for refusing any other.

And firstly, I clothe very warmly indeed. I live in a warm house in the center of London, which, in itself, is much warmer than the country round it. This fact may easily be recognized on a winter day when the snow melts and disappears in London in a few hours, but may lie on the banks and hedges of the surrounding country for more than a week, thus indicating that London is at least two or three degrees warmer than the surrounding country. There are some who believe it is so important to get fresh air that they must of necessity expose themselves to cold in its pursuit; but this is an opinion which I by no means share. Fresh air is said to be productive of a large number of good things, including splendid blood color, but, as a matter of fact, if people live on the right diet they can maintain the best of blood color in London and under conditions of ventilation which some extremitists would possibly characterize as defective; for the truth is that uric acid controls the condition of the blood and a little extra oxygen of the air (though it is, of course, a prime necessity of life), affects it only to a small extent. I hope no one will misunderstand me; I would say to everyone —by all means get all the fresh air you can, but do not imagine that good can be secured by exposing yourself to cold for the purpose. Far more harm will be done by exposing yourself to cold than will be gained from any good the slightly fresher air will do you. It is quite true that oxygen is a necessity, but only one-twentieth or one-thirtieth more oxygen is obtained by flooding a room with cold air, and such a fractional addition does little good. While, if the cold air causes the retention in the body of uric acid in the winter, that uric acid, coming through the blood next spring, will produce far more anemia than would have resulted if the cold air had been excluded and the room properly warmed in the cold weather. It often appears in these matters that people neglect the essential and pay an enormous amount of attention to minor points, not only in the matter of which I am speaking, but throughout the whole of life and in great things as in small.

I, therefore, (as I say) clothe warmly; I live in warm rooms, and though I gain all the fresh air possible, I refuse to live in the open air in the cold weather, looking upon this exposure to cold as a greater evil than a small diminution in the supply of oxygen can possibly be. In the same way it is a wrong course to take a morning cold bath which not only chills temporarily, but for some hours afterwards. This cold comes exactly at the time of the day when the greater part of the uric acid of formation is passing through the blood on its way to the kidneys, and is almost certain to check this excretion and to cause retention. It will thus be seen that cold, and bracing climates, and all tonics, have the same action; they all clear the blood of uric acid and cause its retention. But, if we remember that this is merely "put off, not let off," that every up is followed by a down, and that the retained uric acid must return into the blood at some future time, we shall realize that no permanent good is ever gained by cold baths or any exposure to cold or bracing climates or by tonics, and that our present dependence upon these things is wrong—fundamentally and absolutely wrong, and extremely foolish into the bargain. No doubt those who suffer from collemia as a result of mistaken diet will assert that it is impossible to live without the morning cold bath, the occasional tonic, and the yearly trip to Norway or Switzerland. I thought so once myself, and my life, in my meat-eating days, compelled dependence on stimulant tonics and a yearly holiday at a bracing place. Yet, even then, I could but notice how constantly illness supervened on the return from this holiday, so that the balance of advantage was not unusually on the wrong side. More was lost than gained, and the loss unfortunately came last and produced the more lasting effects. A much better standard than this has since been attained with the knowledge that the previous call for the bracing action of cold, for tonics, and for the spur of stimulants, was nothing but a result of the collemic condition produced by unnatural food, and the simple object now is to be and remain so well that none of these adventitious aids are ever required. This is real health; the other was but disease and the conditions which lead to it, for the tonics and cold bracing climates in curing collemia produce in its place, arthritis, lumbago, or sciatica, and when these are cured in turn by warmth and alkali, the collemia returns with its headache, lethargy, and mental depression. This is a vicious circle from which there is no escape; it is only the swing of the pendulum from one thing to the other, and in the distance bronchitis, Bright's disease, apoplexy, diabetes, or cancer, is the almost certain result. We have yet but a small knowledge of cause and effect, and the

truth is easily missed until ignorance is emphasized by suffering, which enforces a lesson to be learnt on pain of fatal disaster. As it is practicaly impossible for me in normal conditions to live a naturally active life, I am obliged, in addition to these precautions, to take some alkali every day during the cold season of the year. This I take in the form of a bicarbonate of sodium, of which I consume in the coldest weather some 15 or 20 grains in the morning before breakfast, and some 5 to 10 grains in the evening before dinner. In warm weather this is reduced to almost nothing, though even then I often continue a small dose, especially when the mornings are cold.

Some persons have been surprised at my using a drug in this manner, because they believed it was my object to live as far as possible a natural life. To this I can but reply that if, under the unnatural conditions prevailing in this country, and especially in the part where my work must be done, the possibility of a really natural life could be demonstrated, I should pleased to pursue that course, and to give up all drugs, even the bicarbonate of sodium just mentioned. For the same reason that I refuse tonics, I also take little or no salt. It is true that some salt is required in the body to help in digestion, but nature provides for this when it is necessary by creating a crave, and this I always satisfy, though it is only occasionally present. Apart from this I take no salt, for it (chloride of sodium) introduces a powerful mineral acid into the body, and this, diminishing the alkalinity of the blood, tends to retention of uric acid in the body just as do other acids, all metals, and practically all tonics.

But how may a natural life be defined? I think for provisional purposes I should define it as one in which the hours of the working day are evenly divided between bodily activity and sedentary mental work. Many people have too much bodily and no mental activity, and others suffer from too much of the latter and not enough of the former. It seems to me that the natural life should, as far as possible, be the mean between these two, and thus not only proper development of muscles (and hence the best balance of mind and body and the best and most steady nutrition) would be secured, but an increased alkalinity of the blood, and the least possible tendency to retain or hold back in the body the poisonous uric acid would also be obtained. What a pity the poor and the rich cannot each give to the other of their superfluity!

With regard to quality of food I exercise here also, an important precaution. I am careful to eat potato (which contains a considerable amount of alkali), at least three times a day, the potato at breakfast being the most important, though not the most nourishing, item of the meal. I am one of those who do not think it a mere chance that the lowest cancer death rate in the United Kingdom is to be found in association with the largest consumption of potatoes in some of the country districts of Ireland. Cancer, as I have elsewhere pointed out, is associated with retention of uric acid in the body, and next to warmth and natural activity, there is nothing which is more likely to prevent this retention than the humble potato. On the other hand, I am careful to avoid an excess of fruit, for the acids of fruit have, at least for a time, an action exactly the reverse of that of the potato; they cause the retention of uric acid in the body, and, if taken in cold weather, will produce a store of this substance. The rule I follow is simply this—in warm weather and when fruits are in season in this country, take them in reasonable quantity as sauces to the foods, but in cold weather and when there is practically no fruit in season, it is best to abstain from it altogether, and to use potatoes and alkaline vegetables as sauces to the foods instead.

No doubt some will ask at this point, whether fruits and nuts are not the natural food of man? To this I reply that the natural climate of man is in the tropics where fruits and nuts abound, and where it is, therefore, safe to eat them, but by those living in this country, fruit must not be eaten out of season; and since, in addition, all the conditions of life are unnatural we must even condescend to take drugs occasionally rather than set up in the body a store of uric acid.

As I write, I see in one of the daily papers (under the heading "To Stave Off Old Age"), a lavish and somewhat indiscriminating recommendation of an abundance of fruit, and among the fruits so recommended I see citron, lemon, lime, and orange. None of these fruits grow in these latitudes and none of them should, in my opinion, ever be taken here except in the warm season. Yet, there are hundreds and thousands of people who eat these fruits freely in the coldest season of the year. To these I can only say that they must not be surprised when the spring weather brings them debility, lethargy, mental depression, iritability, or even (in some special cases) insanity. If a wrong and unnatural course is pursued, suffering necessarily results. In this country nature has not provided the fruits natural to others where the temperature is warmer, nor do I think it will tend to delay old age to eat these fruits at all seasons, and to store up in the body as a consequence larger or smaller quantities of uric acid, which, coming into the blood later on, must produce high blood pressure, and thus strain and bring about degeneration of the vascular tissues of the body. I venture, on the other hand, to say that if people will follow the course I recommend and practically abstain from fruit from October to April; if they will clothe warmly by night and by day, live in warm houses, exercise reasonably, take potatoes freely in cold weather, and will further, when especially exposed to cold, take a few doses of bicarbonate of sodium, they will pass out day by day all the uric acid they form. And further, never having any excess of this substance, they will avoid undue strain of their vessels, or defective nutrition of the said vessels from that malnutrition of their walls, which is produced by defective circulation from excess of uric acid. They will, therefore, ensure natural and healthy lives, and will do far more to stave off old age and render it useful, beautiful, and natural when it comes than if they use in this temperate region many of the fruit acids of the warm climates.

We may recapitulate the points here brought forward by saying that the greatest freedom from uric acid is obtained by introducing none, and by passing out each day regularly and punctually, all that is formed in the body, and that this regularity of excretion may be attained by clothing warmly, by avoiding exposure to cold in every form, by eating freely of potatoes (especially in cold weather), by avoiding fruits that are out of season, and indeed by never taking fruit[1] to any large extent, except in very warm weather. It is also advisable to secure the proper distribution of time between bodily and mental exertion, and to dispense with dependence on tonics, stimulants, and bracing climates. The result will be a better balance of mind and body, and a more healthy, natural, and useful existence than has been generally experienced either by ourselves or by our ancestors in the previous century.

[1] These rules are for those in a more or less satisfactory physiological condition and have no bearing on special diets, such as that of bread and fruit, given in special conditions of disease and for a short time only.

# LONG ISLAND APPENDICITIS.*

By A. ERNEST GALLANT, M.D.,

NEW YORK.

PROFESSOR OF GYNECOLOGY, NEW YORK SCHOOL OF CLINICAL MEDICINE; CONSULTING SURGEON, JAMAICA HOSPITAL, JAMAICA, L. I., ETC.

Why Long Island appendicitis? Because in the cases under consideration the patients were all residents of Long Island. Because the diagnosis was made by a Long Island physician, who prepared the patient for and assisted at the operation, the anesthetic being administered by a Long Island practitioner, and the after care carried out by the Long Island family physician, with a mortality so low as to compare very favorably with any and speak very highly for the Long Island doctors' exercise of good judgment during convalescence, leading to an early return to health and strength.

The cardinal symptoms of an acute attack or acute exacerbation of appendicitis are pain, nausea and vomiting, fever, right-sided abdominal rigidity, and tumefaction. The pain, nausea, and vomiting, and fever are always present the first day, and in 2,000 cases reported by J. B. Murphy in the *American Journal of the Medical Sciences,* CXXVIII, 1904, p. 187, always presented in the order named.

The onset of appendicitis is first announced by sudden and severe abdominal pain, general throughout the abdomen, rapidly growing worse, attaining its maximum within a few hours, followed by general abdominal tenderness, with localization of the pain in the right iliac fossa. This pain may gradually diminish, and the patient recover without further difficulty until the next attack. A sudden cessation of pain takes place (*a*) after the appendix empties itself into the caput coli, (*b*) after rupture, or (*c*) gangrene of the appendix; but the absence of pain must not lead to the false idea that the danger has passed. The recurrence of pain in the right iliac fossa during the second day or later shows that the infection has extended outside the appendix, that the process is progressing, and that the appendix, if not removed, the sooner the safer, will endanger the life of the patient. Every hour's delay can only add to the difficulties when removing the diseased organ and diminish the chances for ultimate recovery.

Next in order after the initial pain, perhaps within the second or third hour after its onset, at latest during the first day, vomiting or attempted vomiting may occur for a few times, then cease and never recur. Should it do so, it will indicate that rupture with leakage has taken place or that the general peritoneum has been infected, and if unrelieved a fatal issue may result.

Soon after the primary pain of appendicitis begins an elevation of temperature can be determined. This is always present, and the earlier the temperature the more acute the infection. The higher the fever the greater the absorption of toxins, indicating that the pus is *for the time being* walled off under great tension, and liable to rupture at any moment or on the application of injudicious pressure by the examiner's hands. After the appendix empties itself into the cecum the temperature may not rise again; after rupture or gangrene the temperature may suddenly drop, and later run up to 102° to 103° F., in which case the gangrenous process is extending, the pus has become walled off, or the infection has spread throughout the peritoneal cavity—in either case a condition indicative of serious lesions and demanding operative interference.

A normal temperature and slow pulse after the primary elevation has subsided do not always indicate freedom from danger, as shown by the case of my own brother, who for three days prior to operation had a temperature of 98.6° F., pulse 60, and was walking about the room, complaining only of a little soreness in the right iliac region when using the leg, yet we removed from the fossa a gangrenous appendix, which had sloughed entirely off and was embedded in a considerable mass of exudate. He recovered without any rise of temperature.

When called upon to decide at once the question "to operate or not to operate?" my chief reliance has been on the information derived from abdominal, abdominopelvic or abdominorectal palpation most carefully carried out. In many instances one can determine the specific variety of the disease he is dealing with before opening the cavity, and decide upon the most advantageous position for the incision, a point that is especially important in women, in whom it is often necessary to operate upon the uterine adnexa when removing a diseased appendix.

As you are well aware, the position of the appendix has much to do with the location, feeling, and size of the tumor, as determined by palpation and percussion, as in the following instance:

Case I.—Miss S. M. Right iliac fossa filled by a mass lying obliquely toward the symphysis and median line; tympanitic on percussion. McBurney incision disclosed the caput coli displaced forward and inward from behind, the false pelvis filled with white exudate, forming a mass the size of a mandarin. Caput lifted up and the perforated appendix found curled up behind. No pus pocket found. Sterile gauze packed to the outer side for drainage. One week later the exudate had softened and was rapidly absorbed. Temperature 98.8° F., pulse 84.

Owing to rigidity and distension it is not always possible to locate a tumor, and one must be guided by the history and the general condition of the patient and the findings after anesthesia has been induced as in this case:

Case II.—Retrocecal appendicitis: Master O. M., 6 years old. Very ill for several days; abdominal pain and distention, constipation, temperature 103° F., pulse 120 for past two days. Bowels have not responded to calomel taken last night. Vomitus green. Abdomen, especially on right side, very tense, tympanitic. Just prior to etherization, temperature 101.4° F., pulse 120. The boy looks septic. Under ether a mass can be made out extending from the pelvic brim upward along colon; this gives a tympanic note. McBurney incision through the skin shows edema of the subcutaneous tissue. Considerable serum escaped before cutting through the muscles. On worming the index finger between the caput and the fossa, an abscess cavity was opened, exposing considerable exudate and sloughing material, among which the appendix could not be found, but its former site was traced by the longitudinal colonic band, as it had been entirely destroyed by the gangrenous process. The cavity was wiped dry, irrigated with peroxide of hydrogen, and packed with sterilized gauze. The abdominal wound was partially closed by tier sutures.

Under some circumstances the presence of a tumor cannot be positively defined, and in children at times it must be determined by rectal or vaginal examination (if old enough) after anesthesia has been established.

Case III.—Perforated, gangrenous appendix, with pelvic abscess. J. McN., 7 years old. Examination of the abdomen demonstrates general distention and tympany; enlargement of the veins of the lower right quadrant, but neither a mass nor the appendix can be made out. The child looks decidedly septic. Under ether, through the rectum a mass

*Read by invitation before the Suffolk County Medical Society, Riverhead, L. I., April 27, 1905.

can be felt on the right side of the pelvis, and on bimanual examination it is distinctly fluctuant. The appendix was found hanging down in the pelvis, 3½ inches long, curled on itself, with three points of gangrenous perforation. While following the appendix into the pelvis the finger passed into a pus sac containing more than two ounces of very foul smelling pus. Dressed in the same way as the preceding case.

Case IV.—C. G. There was a well-marked tumor visible through the abdominal wall, most prominent at McBurney's point, which was made up of omentum, the curled appendix and exudate lying in front of the cecum. The omentum was ligated and cut away, the appendix excised, the exudate wiped away, the cavity washed out with peroxide and saline solution, and the abdomen closed. Eleven hours later his temperature was 98.4° F., pulse 68.

In women the diagnosis of appendicitis is at times obscured by pelvic disease, especially in those not uncommon cases in which the ovaries and tubes have developed high up posteriorly at or above the brim.

Case V.—When first seen by the writer this patient was thought to be suffering from appendicitis, but on palpating the appendix nothing active could be made out, and as there was a history of old pelvic disease, it was deemed advisable to defer operation. Two months later she came to the city, and I curetted the retroverted uterus, removed a cystic appendix, and suspended the uterus through a median incision. The appendix was attached normally; the right ovary and broad ligament were held by firm bands to the right pelvic brim.

*Mortality.*—Up to August, 1904, it was my good fortune not to have lost a patient upon whom I had operated for appendicitis, and it seemed that every case of Long Island appendicitis cared for by a Long Island physician would recover. From this pleasant dream came a rude awakening.

Case VI.—Gangrenous appendicitis, general peritonitis, intestinal obstruction, death. E. M., 3 years old. During past five days has been ill in bed with "stomachache." Had complained of some tenderness for a week before going to bed. Vomited yesterday after enema, but bowels did not respond, nor had they moved prior to operation. Abdomen distended, fairly soft on left, rigid on right; a large mass occupies the right iliac fossa and extends obliquely inward and downward toward the symphysis pubis. Through an oblique incision the lower part of the ileum was found against the anterior wall, securely walled in by exudate. A finger passed along the outer side of the caput entered a sac from which there escaped six ounces of thin, yellowish pus, of a distinctly fecal odor. With considerable difficulty, owing to the short mesoappendix, the appendix was removed. After clearing away the exudate, freeing adhesions, and saline irrigation, the wound was closed without drainage. Prognosis good if bowels move. This did not take place, and she died the second day after operation.

Case VII.—Gangrenous appendicitis, congenitally displaced ascending colon; spastic contraction of the colon; death. M. S., 16 years old. Five days ago not feeling well; pain in abdomen, constipation, very nervous, nauseated. On third day vomited. Temperature 102° F., pulse 110. Fourth day, expulsive vomiting, abdomen tense. Fifth day, tympany and tenderness over whole abdomen, lower half rigid, especially the recti, behind which lies the displaced colon. Nothing made out in either iliac fossa. Temperature 102° F., pulse 110. Through an oblique incision the ascending colon was found lying in the median line, attached to the right ilium by a mesocolon six inches long (congenital). The gangrenous appendix, which lay behind the caput coli, had broken off and communicated with the cecum, though no intestinal contents could be seen in the abdominal cavity. The gangrene involved all but a half-inch of the appendix, had extended to the adjacent structures, and was not walled off by any adhesions. The intestines were of a very dusky hue, the ascending and transverse colon were markedly distended, the middle of the descending colon was in spastic contraction, and the peritoneum covering the small intestines was markedly injected, but free from exudate. The stump was inverted, the gangrenous area treated with hydrogen dioxide, the cavity with saline solution, and the abdomen closed. After operation the symptoms of peritonitis continued, and she died the following night, thirty hours after operation, six days after the onset of the disease.

*Interval Operations.*—When, in 1899, the writer first began to operate on Long Island, the mortality from appendicitis was said to be quite high, due in part to late recognition, late operation, or failure to operate at all. The more careful study on the part of the physician, that has made him feel positive as to his position in making a diagnosis and insisting on early operation, coupled with the dearly bought knowledge on the part of the layman that early operation is the one thing which can with certainty save him when he is attacked by acute appendicitis, has brought about such a change that during 1904 the writer removed the appendix in several instances shortly after mild or recurrent attacks. The wisdom of this course is shown by the fact that these patients convalesced without temperature, remained in bed only seven to ten days, and returned to business in two weeks. When we compare this result with the risks incident to a severe infection in an appendix, the seat of changes, due to recurrent attacks, one cannot wonder that our patients soon come to accept and demand the removal of the appendix as soon as the first mild attack has subsided, for each succeeding attack is more likely to be more serious than its predecessor.

*Complications Following Appendectomy.*—Operations during an acute attack must at times be carried out under unfavorable circumstances.

Case VIII.—Grip, appendicitis with abscess, hypostatic pneumonia, empyema, recovery. F. H., 19 years, has had several attacks of appendicitis, and was advised to submit to interval operation, but procrastinated. Examination shows a large mass filling right iliac fossa, plainly visible through the wall. For past few days has been troubled with grip cough; mucous rattling can be heard in chest. Through a McBurney incision a sickle-shape appendix was found lying between the abdominal wall and the caput coli, with several ounces of foul-smelling pus. Peroxide and saline irrigation. Wound closed in layers. About four months later he came to town, and after resection of two ribs, made a slow but very satisfactory recovery. What a striking commentary on the wisdom and advisability of interval operation and the unwisdom of disregarding that advice!

If handled properly, fecal fistula usually can be closed at the original operation, or they contract and close without secondary operation, but this did not occur in the following case:

Case IX.—Fecal fistula, end-to-end anastomosis, recovery. The original operation, in one of our Brooklyn hospitals, left a fecal fistula still discharging at the end of six weeks. After dissecting the tract down to the gut, it was found necessary to excise two inches of small intestine and suture it

end to end, with closure of the abdominal wound in layers. This child made the most satisfactory recovery it has ever been my good fortune to observe—painless throughout—and after the second day it was difficult to keep her in bed. She did get out of bed on the seventh day, and walked about the ward on the tenth day.

When the appendix opens on the skin and its lumen is shut off from the bowel at its proximal end, we shall be troubled by a mucous discharge or the intermittent escape of muco-pus, as in this instance:

Case X.—Appendicular fistula, excision of appendix, recovery. This boy of 9 years was operated on for an appendicular abscess about eighteen months ago, and since then two attempts have been made to close a sinus at the site of the primary incision. On dissecting around the fistula it was found to consist of the appendix, which communicated with the surface. On account of the great amount of cicatricial tissue from the previous operations, the wound was closed with difficulty, but it healed kindly, though I feared a hernia might follow.

After you have listened thus patiently to this simple repetition of "the old, old story," permit the writer to enumerate the rules which, from a considerable personal experience and the study of many thousand cases recorded by other observers, he has formulated for his guidance when called upon to decide "when to operate for appendicitis."

1. With a history of sudden, sharp abdominal pain, soon followed by nausea and vomiting and fever, appendicitis may be surmised, and if a little later the pain becomes localized or most intense in the right iliac region, with right-sided rigidity, the diagnosis stands confirmed.

2. The "safe" treatment of acute or recurrent appendicitis during the attack is operation within the first forty-eight hours following the primary pain.

3. If toward the close of the second day, in spite of an icebag continuously applied over the appendicular region and free castor-oil evacuation of the bowels, the pain and rigidity, with or without nausea and vomiting, temperature and pulse elevation, continue or return, to delay operation under such conditions can only subject the patient to the danger of rupture, extensive gangrene, general peritonitis, intestinal obstruction, and a fatal issue.

4. In the presence of a mass or of tumefaction delay is dangerous—operate at once.

5. Interval operation is free from danger, requires but seven days in bed, two weeks from business, and gives freedom for life.

60 West Fifty-sixth Street.

## LACERATIONS OF THE CERVIX UTERI.*

By ARTHUR H. GARDNER, M.D.,

NEW YORK.

Most obstetricians agree that laceration of the cervix occurs to a greater or less extent in nearly every labor. This idea is so firmly fixed that if a cervix is seen without some sign of laceration it is believed to belong to a nullipara. Bernhardy has said that about 25 per cent. of all of these lacerations heal spontaneously. In 75 per cent. the women are either operated upon or the laceration remains.

As to the amount of harm resulting from unrepaired lacerations, there is a great diversity of opinion. Emmet said that at least one-half of the ailments of women who have borne children were to be attributed to lacerations of the cervix uteri. Although it was Emmet who first realized the train of symptoms which may arise, and although his statement was made years ago, in the enthusiasm of having found a remedy for a very frequent cause of suffering, the more mature judgment and experience among gynecologists teach that although there is exaggeration in this statement, there is much truth.

Hirst says that "the result of a bilateral or stellate tear, or of extensive cicatricial infiltration, is a never-ending local irritation, leading to chronic congestion, not only of the cervix, but of the whole uterus; to endocervicitis and endometritis; to cervical catarrh and a consequent leucorrhea. There is always danger of epithelioma from the constant and long-continued irritation, the vast majority of these growths having their origin in an old injury of the cervix. . . . It is possible also to witness a varied train of neurasthenic and reflex symptoms, referable to these lacerations, only disappearing after repair; but the influence of cervical injuries has been much exaggerated in the past, and the physician must guard against attributing too much importance to the local lesion, in a neurasthenic individual with impairment of the general health."

Taylor says that "the lacerated cervix, although minor gynecology, has an important bearing upon what is, perhaps, still the gravest disease to which a woman is subject—puerperal septicemia. Death may be a not infrequent consequence of acute septic laceration of the cervix. Laceration may: (1) interfere with proper involution, which causes the sensation of weight, menorrhagia, backache, etc. (2) Interfere with the position of the uterus, causing a sagging to one side when the laceration extends into the broad ligament, thus creating a dragging pain. (3) Have an effect upon the nutrition of the cervix. Everted mucous membrane becomes irritated and infected, resulting in endocervicitis, pain on coitus, sterility, abortion, etc. (4) Have an effect upon the wall of the uterus at the angle of the tear. The wall becomes thin and yielding. Epithelioma is rarely a result. Lacerations of a minor degree are of no importance."

Baldy has no sympathy with views attributing reflex symptoms to these lesions. He believes that the symptoms from laceration are essentially local—constant leucorrhea, feeling of weight and uneasiness in the pelvis and about the rectum, which is due to the size and inflammation of the cervix itself. "This is not infrequently added to by a displaced fundus, an endometritis, prolapsed ovaries, an inflammation of the ligaments radiating backward from the cervix, or by a general sagging downward of the uterus, with relaxation of its supports. When these complications occur, and the patient has been a long sufferer, it is easy to understand how she may become neurotic and a sufferer from all the ills of chronic neurasthenia."

Craig says that "American authorities unanimously agree that local traumatism predisposes to future malignancy, and the exceptions seem to prove the rule. In England the statement should be exactly reversed. At least 90 per cent. of the cases of cervical carcinoma occur in previously lacerated cervices remaining unrepaired." He says that he is convinced that irritation of the cellular elements on the everted, eroded lips of a laceration, predisposes to cancer.

Morse says: "Looking at the sequelæ of laceration from another point of view, we find that carcinoma of the cervix is far more frequent in multiparæ than in nulliparæ, while carcinoma of the body of the uterus is about of equal frequency in both."

* Read before the Society of the Alumni of the Sloane Maternity Hospital, January 27, 1905.

Palmer says: "The relation between laceration of the cervix and malignant disease of the uterus (where it is detected five times more frequently than elsewhere in a woman's body except in the mammary gland) is so forcibly demonstrated as cause and effect that all physicians should recognize it."

Godson, on the other hand, does not believe that lacerations of the cervix have any predisposing influence in the etiology of cancer, and Baldy says that no one has, to his knowledge, as yet produced a single scientific fact which would uphold such a theory.

Nearly all accoucheurs agree that cervical tears, resulting in hemorrhage, should be immediately repaired by means of suture. Some writers on the subject, even within the last few years, consider styptics and tamponage as means of controlling such hemorrhage, but it hardly seems good surgery to depend upon these, when it is so easy to apply a few sutures.

In regard to the repair of moderate and severe lacerations not resulting in hemorrhage, it has been amazing to me to find so much indifference and divergency of opinion. In reviewing the text-books on obstetrics of the last fifteen years, I find that the following writers do not discuss nor even consider the repair of cervical tears which do not result in hemorrhage: Playfair, Parvin, Norris, Martin, Ribemont, Dessaignes, G. Lepage, Reynolds and Newell, Pozzi, Vogel, Runge, Spiegelberg and Wiener, Schroeder, Gallabin, Tarnier and Budin, Fothergill, Evans and Gallaudet, Kaltenbach, Dakin, Bumm, Manton and Bushong, Olshausen and Viet, and Lusk consider only the repair of extensive lacerations. Cragin says that unless there is hemorrhage, suture is seldom resorted to. He thinks that if immediate or intermediate repair were done by skillful hands in a well-equipped maternity hospital, good results might be obtained.

Among obstetricians who recommend repair of the cervix, a terminology relative to the time of operation has come into general use within the last few years. By immediate repair, we mean a suture of the laceration directly after delivery, or within an hour or two. By intermediate repair is meant a suture of the laceration five days after delivery, or later during the puerperium. The term *remote* repair is applied to a suture any time after the puerperium.

The writers who recommend immediate repair are Newell, Grandin and Jarman, Davis, Coles, Jellett, Bacon, Palmer, and Stone.

Those recommending intermediate repair are Hirst, Dickinson, Goodell, and Norris.

Those who recommend a remote repair are Haven and Young, Jewett, Webster, Warren, Müller, Craig ("American Text-Book of Obstetrics," 1895), Dorland, Baldy, Cragin, Burtenshaw, Edgar, Williams, Wakefield, and Holmes.

Let us consider the advantages and disadvantages of the different times for operation, as set forth by their respective advocates and opponents.

*Advantages of the Intermediate Operation.*—1. It requires but a few minutes, which can easily be added to a labor, no matter how long the labor has taken.

2. If the woman has come out from the effects of her anesthesia, a few whiffs of chloroform is all that is necessary. If none is given, and it is particularly desired to give none, the operation is almost painless.

3. It does not make a secondary operation necessary, thus causing less inconvenience to patient and surgeon.

4. It can be done at home or in the hospital.

5. It prevents sepsis by closing an avenue of entrance to bacteria.

6. It removes the most frequent cause of subinvolution.

7. No particular operation, device, or instrument is necessary.

8. It gives almost as good a result as we get from suturing perineum, pelvic floor, or anterior vaginal wall.

9. It has usually proved successful in the hands of able surgeons.

*Disadvantages of Immediate Repair.*—1. In perhaps 25 per cent. of cases no repair is necessary, as healing takes place spontaneously in about this percentage of cases (Bernhardy).

2. The cervix is "swollen, distorted, and stretched beyond recognition" (Dickinson); this makes suture difficult.

3. "Bleeding obscures field of work" (Dickinson).

4. "Puncture points of needles bleed about as freely as do the torn surfaces" (Baldy).

5. "Sepis may be carried by fingers, sutures, and instruments."

6. "Traction upon the uterine ligamentous supports at this time may be productive of uterine prolapse and retroversion."

7. "Manipulation at this time may cause embolism."

8. "When shrinkage takes place the wound surfaces are exposed to infection just the same as before suture" (Baldy).

9. "Sutures in the swollen cervix hang like rings after contraction and involution, and thus do no good" (Hirst).

10. "It may interfere with drainage."

11. We must have assistance.

12. Deliberation and due care are impossible at this time.

13. There is a bad effect upon the morale of the patient.

Some of these reasons are evidently prejudiced and the objections are palpably puerile.

*Advantages of Intermediate Repair.*—1. Less danger of infection. Hirst says that previously to his advocating intermediate tracheloplasty, when he was suturing after delivery, he had an occasional infection. He feels from his experience that there is much less likelihood of introducing sepsis if the operation be done five days after delivery.

2. The swollen and edematous cervix has contracted by this time, so that approximation is more accurate and permanent.

3. The woman is in better condition.

4. The accoucheur can arrange time and assistance to suit all concerned.

*Disadvantages of Intermediate Repair.*—1. A secondary operation breaks into a woman's convalescence in a most unpleasant manner. She has to take an anesthetic, with its possible train of discomforts, at a time when the milk secretion is fairly established, and the baby is nursing well.

*Advantages of Waiting for Symptoms and of Remote Repair.*—1. By waiting we will not find suture necessary in the approximated 25 per cent. of cases, which heal spontaneously.

2. Some women, with moderate tears, never have any symptoms.

3. Sometimes treatment will relieve symptoms, making it possible to do without the dreaded operation.

4. It is easy to choose time, place, and assistance.

*Disadvantages of Waiting for Symptoms and of Remote Repair.*—1. Many women will bear pain and suffer for years before consulting a physician.

2. The long train of nervous and hysterical symptoms, arising from laceration, with their complicating pathological pelvic conditions, may so undermine a woman's health before she seeks advice, that it may require a long time for restoration to a normal condition, even after the tracheloplasty has removed the cause.

If it be true, as Bernhardy has said, that about 25 per cent. of all lacerations heal spontaneously, the question naturally arises, why do not the other 75 per cent. heal spontaneously? There are probably at least three reasons. (1) Lacerated wounds of the cervix, as in other parts of the body, may, with no interfering factor, as sepsis, heal by granulation, and more or less eversion of the wound edges, depending upon the tension in the parts divided. (2) Sepsis entering the divided surfaces causes suppuration and necrosis, with slow exuberant granulations, and eversion of the edges. The ultimate result in both of these conditions will be a formation of scar tissue, which is generally believed to be a factor in producing morbid conditions. (3) The introduction of the douche nozzle, tampons, etc., prevent approximation of the wound surfaces.

A prominent gynecologist recently told me that he believed that it was not the laceration itself which caused the symptoms usually ascribed to it, but the concomitant sepsis, with its resulting pathological changes. If no sepsis enter, will all lacerations heal? If it be sepsis which prevents healing, there must be an enormous number of puerperal cases, which have been more or less septic.

It will be noticed that both those who recommend immediate and those who recommend intermediate suture, claim advantage in preventing the entrance of pathogenic bacteria, on one hand, by closing the avenue, and on the other, by not introducing instruments, catgut, etc., which may carry infection. The obstetrician who understands asepsis does not fear carrying infection with his instruments.

Should students be taught to repair a lacerated cervix immediately after delivery? Hirst feels that students should be taught to do their obstetrical work as it ought to be done. Cragin does not sanction its being taught to students. It seems inconsistent to teach medical students to do all sorts of operations on other parts of the body, and yet not to approve of their learning the value of placing a few sutures in the puerperal lacerated cervix.

But the facts remain that the family physicians always have, and perhaps always will, practice obstetrics, and that the family physician is often one who does not understand, nor practice asepsis. Without absolute asepsis, it would be criminal to attempt any post-partum surgical procedures upon the parturient canal, as much so as to attempt to do a laparotomy without such precautions.

The method of procedure in immediate repair is very simple. The patient should be placed upon a table, and in proper position, so that the cervix can easily be drawn down into good view with volsellum forceps. With the wound sponged and exposed, a few plain catgut or chromicized gut sutures can easily be inserted, and we have finished the simple operation.

*Conclusions.*—1. Many ills are the result of unrepaired lacerations of the cervix.

2. The frequency and extent of these tears may, to a certain extent, be lessened by allowing more time for dilatation in the first stage of labor; by a more judicious use of the forceps in time and force; and by the proper use of podalic version.

3. The most frequent cause of subinvolution of the uterus and prolonged convalescence is unrepaired lacerations.

4. In all probability many of the frequently quoted morbid conditions ascribed to lacerations are the result of infection of the lacerated surface rather than the laceration itself.

5. Many cases of severe hemorrhage are due to unrecognized cervical lacerations.

6. Immediate repair in the hands of an able surgeon-obstetrician is the best means of controlling such hemorrhage, and also of preventing infection of the torn surfaces.

7. Primary tracheloplasty is easily and quickly done, but a secondary repair is a difficult and tedious procedure.

8. In case of failure in obtaining union in the primary operation, the condition of the woman is none the worse, while if successful, which is usually the case with skillful surgeons, the patient is spared many of the ills which lacerations of the cervix sooner or later entail.

9. In regard to teaching medical students, it seems as if the matter should be fairly placed before them. Where hemorrhage persists with a well contracted fundus, they should be taught to look for spurting vessels in the lacerated cervix, and to suture. As to immediate repair without hemorrhage, they could be taught its advantages, and as in other departments of surgery, they should have deeply impressed upon their minds the evils which might arise from poor technique and lack of asepsis.

## CASE OF DELAYED MENSTRUATION; FLOW ESTABLISHED AT FIRST SPONTANEOUSLY, SUBSEQUENTLY BY TREATMENT; CONCEPTION.

BY B. P. HIRST, M.D., AND HERBERT FOX, M.D.,

PHILADELPHIA.

We present the notes of a woman who had no menstrual flow until the thirty-fourth year, then menstruated spontaneously three times. After an amenorrhea of five months she responded to treatment, and shortly conceived. We have found only one more remarkable case than ours. Wolfe (*Lancet*, ii, 1898, p. 323) reports the history of a woman who married at 34, menstruated first at 45, conceived, and was delivered at 46 years. The first bleeding followed immediately upon a fright.

The late institution of menstruation, after the 30th year, is very rare. Winckel (Handbuch der Geburtshülfe, I, 1, s. 94) states that it occurred only once in 34,000 cases in which the date of the first menstruation was obtained.

A. A., housewife, æt. 35, white, married ten years, German. Her mother died of some lung condition at 54. Father at 76, of senility; three brothers died in infancy; three half-brothers living and well. She came to America in her seventeenth year; she was always healthy. Six years ago she fell downstairs, a newel post striking the abdomen over the liver, rupturing its superior ligament, producing a hepatoptosis of five finger-breadths and considerable muscular bruising. She was kept in bed for six weeks, during which time, and for two months later, she was firmly strapped from the crest of the ilium to the lower margin of the breast, and received frequent light massage. She wore a belt after that for about a year. There were no uterine disturbances or hemorrhages from any organ. She never had a sign of menstruation until she was 33 years

old, when, in April, 1903, without apparent cause, she bled profusely for five days, with dull pain in the lower abdomen the first day. Four months later she had a period of eight days' duration, accompanied by severe abdominal and sacral pain, the flow consisting of dark, thick fluid blood. Six weeks later she was again unwell, without pain, for four days; the discharge was bright fluid blood. In February, 1904, there having been no menstruation for four months, Dr. Girvin, at the Presbyterian Hospital, found the following condition: Vulva and vagina normal; cervix small and soft; uterus infantile and soft, freely movable, in good position; right adnexa not palpable; left adnexa normal. He advised a general tonic and a daily borax douche for leucorrhea. This discharge had been present for fifteen years, and was yellowish, slightly foul, and quite irritating. It was always worse after exertion or excitement; it had stopped for a few days after each of the three periods.

The blood examination showed the following: Hemoglobin, 76 per cent.; erythrocytes, 3,800,000; leucocytes, 7,800. She was given a pill of arsenic, quinine, and strychnine, and a pill containing aloin, extract of belladonna, and strychnine, for persistent constipation. At the same date in each of the two months preceding this treatment she had experienced peculiar symptoms of dizziness, backache, and dull abdominal pain. Assuming that at these dates a normal menstruation should have occurred, we introduced a boroglyceride tampon a few days before the corresponding date of March, 1904, with the result of a painless menstruation of bright fluid blood, lasting eight days. In April, however, no bleeding occurred, although the same treatment was administered. In May a menstruation appeared at nearly the correct time, accompanied by moderately severe pain the day preceding and on the first and second days. Treatment was continued until, in October, her blood examination showed hemoglobin, 87 per cent.; erythrocytes, 4,400,000; leucocytes, 7,200; but since June there had been no menses. A pelvic examination discovered pregnancy, apparently about the fourth month.

She was admitted to the Maternity Department of the University Hospital on March 4, 1905. The date of expected delivery could be set only approximately in March, since the date of conception could not be determined. She was delivered on the 8th of April, which would indicate that conception occurred probably in July, more than a month after the last menstruation. Quickening was observed about four and one-half months before labor. The labor, which began at 8 P. M. on April 7, progressed slowly but steadily until the descent of the head to the pelvic floor, at 12 M. on April 8. After waiting four hours, the Sawyer forceps was applied, and delivery was completed without difficulty.

## SERUM THERAPY IN ERYSIPELAS; RESULTS IN THIRTY-THREE ADDITIONAL CASES.

By JAMES C. AYER, M.D.,
NEW YORK.
ADJUNCT ASSISTANT SURGEON, BELLEVUE HOSPITAL.

Some months ago I reported my observations on a series of fifteen cases of erysipelas treated by antistreptococcus serum; and in this paper I shall give the results obtained by the same treatment in thirty-three additional cases.

In tabulating the data of these cases, I have laid especial stress upon the following points: Treatment begun (day of disease); desquamation begun (days after first dose of serum); duration of disease; number of injections and total amount of serum given; initial leucocytosis; leucocytosis at desquamation; initial albuminuria present, and day of its disappearance after first dose.

Of the thirty-three cases, three patients died (9 9/10 per cent). One, an infant, died on the eighth day of the migratory form of the disease; the second, of lobar pneumonia, and the third, of wet brain.

Only those patients received the serum who were admitted to the hospital on or prior to the third day of the disease, as I regard its administration after that period as useless. The average duration of the disease under these conditions was 6 8/10 days; and, based on the period at which treatment was begun, was as follows:

| | | |
|---|---|---|
| First day, | .... 2 cases.. | duration, 7½ days. |
| Second day | .... 10 cases.. | " 7 days. |
| Third day | .....21 cases.. | " 6 9/10 days. |

The desquamation began on an average of 3 6/10 days after the first dose of serum.

The amount of serum used in each case averaged about 20 c.c., given in one or two doses.

The initial leucocytosis was uniformly high, averaging 17,540, while the counts made on the day of desquamation showed an average of only 8,500.

An initial albuminuria was present in 40 per cent. of the cases, over one-half of which cleared up by the second day after receiving the serum. In the remainder, the albuminuria still persisted at the time of the patient's discharge from the hospital.

Of these cases, thirty-two were of the facial type, and one migratory. Most of the latter type of cases which I have encountered have been in infants, and they almost invariably terminate in death.

I have also remarked that the facial types predominate in the winter, while in the summer the disease is located on the extremities in a considerable number of cases.

In this last series, the average duration of the disease was 6.8 days, as against 7.6 days in my previous series. In my first series of 79 cases treated by the older methods, the average duration was 9.4 days.

This shortening of the average duration of the disease by 2.6 days about expresses, to my mind, the value of this form of treatment. The general amelioration of all the subjective symptoms following its employment is also in its favor, as is the apparent beneficial effect on the febrile form of albuminuria which is present in such a considerable percentage of the cases.

---

**Is Tuberculosis a Causative Factor in the Production of Cancer?**—A. Hamilton Levings reports sixty-one cases of cancer, 70.2 per cent. of which gave a distinct family history of tuberculosis. In the majority of the sixteen cases in which the reports did not show tuberculosis in the families, the histories were incomplete. The writer believes that the theory held for centuries, that there is a distinct antagonism between tuberculosis and cancer, must, in the light of present knowledge, seem disproved. For, he adds, the two diseases may attack not only the same patient, but lie side by side or intermingle. The writer is impressed with the seeming fact that malignancy never attacks perfectly healthy and normal tissue. It makes its inroads rather on tissues that have a lessened vitality, and which have been weakened by inheritance, by traumatism, or by chronic inflammation. He thinks that at the end of the next hundred years or two, tuberculosis will practically have disappeared in consequence of improved hygienic conditions, and man, having become then stronger and more resistant, will not be attacked by malignant disease to nearly so great an extent as he now is.—*The Clinical Review.*

MEDICAL RECORD.

## BASIC PULMONARY TUBERCULOSIS.

WE believe it was Gerhard who used to make a point of constantly admonishing his pupils to keep in mind the fact that rare conditions, although of exceptional occurrence, were really encountered from time to time, and must be looked out for. The law of probabilities always plays a great part in deciding doubtful questions of a medical diagnosis, but if followed too inflexibly it sometimes leads to grave mistakes. It is natural, for example, to associate the thought of incipient pulmonary tuberculosis with an apical lesion, and in the vast majority of cases the disease does begin at one apex. It is, nevertheless, true that in a certain small percentage of consumptives the morbid process starts at the base of the lungs, instead of in the upper portion of the upper lobe, and it is well not to lose sight of this possibility.

This mode of origin of pulmonary tuberculosis is made the subject of a contribution by Dr. Herbert C. Clapp and Dr. George N. Lapham (*New England Medical Gazette,* August, 1905), based on the statistics of the Massachusetts State Sanatorium for Consumptives, at Rutland, Mass. The authors first say that in calling attention to the base of the lung as a location for the deposit, they wish to have its exceptional character prominently brought forward. This fact is emphasized particularly because of the knowledge, gained in teaching, that the human mind, by a queer process, unless it is warned is very apt to remember exceptions almost as well as the rule, and sometimes even better. A paper on this subject would therefore be worse than useless, unless by calling attention to the extreme rarity of the exceptions it served to prove the well-nigh universal application of the rule. As to just exactly how rare this form of the disease is, the few statistics which are accessible do not agree. Louis, in his classical work, "Recherches sur la Phthisie," reported two cases out of 123. Dr. Walsh gave one in sixty or eighty; Dr. Cotton two in 1,000. Dr. Pollock, in his famous "Prognosis in Consumption," gave sixty-four cases in 4,530 (or one in seventy) in which the physical signs were most marked at the base from the commencement. He states that just one-half, or thirty-two, had also signs of incipient disease at the apex when examined. It must be remembered, however, that all of these investigators lived and wrote before the discovery of the tubercle bacillus, and undoubtedly from the symptoms often considered cases as tuberculous which we now should class as non-tuberculous on account of the negative results following repeated examinations of the sputum during life, or on account of the absence of the bacillus in the tissues post mortem. Four years after Koch's discovery, Dr. Percy Kidd published an interesting article on this subject (*The Lancet,* 1886, ii, pages 615 and 665), in which he very properly refused to classify as basic those affections of the apex of the lower lobe which are not infrequently met with. He reports two cases with autopsies as the only examples of true basic tuberculosis he met with in 412 cases, in all of which he made the post-mortem examinations himself. This would give one in 206. He thought it very likely, however, that a larger number of autopsies would still further reduce this proportion, and that probably one in 500 would not be far wide of the mark. The authors then go on to discuss the statistics recently gathered from the records of the Massachusetts State Sanatorium. This institution has treated 3,252 patients during the six and one-half years of its active existence. Among these were but five patients whose disease, as indicated by the physical signs, was located only at the base of the lung, and in whom at the same time the tuberculous nature of the process was satisfactorily proven—in four by finding tubercle bacilli, and in one by the tuberculin test. A number of cases of what at first seemed to be basic tuberculous disease were excluded from the list because, although the symptoms and physical signs of phthisis were present, one could not, in the absence of tubercle bacilli or of a positive tuberculin test, be really sure of their tuberculous nature, as would have been possible had the diseased portion been apical.

Some of the basic diseases which simulate tuberculosis are unresolved chronic pneumonia of the lower lobe, the pneumonic condition and bronchiectasis resulting from a foreign body in the bronchi, collapse of the lower lobe, and cirrhosis following pleuritic effusion, empyema opening into the lung, etc. Any one of these, however, may subsequently receive tuberculous infection, so that the search for the bacilli should be continued at proper intervals. These five cases out of 3,252 give a ratio of one to 650. Thinking that this proportion might be a little unfair, owing to discrimination against basic cases in admitting patients, on account of a feeling that their prognosis is less favorable than that of the commoner kind, the authors counted up the number of basic cases among the 6,769 consecutive applicants for admission during the last four years and six months. Out of these 6,769, they found thirty-two cases in which the physical signs indicated basic trouble. Of these thirty-two, however, only eight showed tubercle bacilli in the sputum, although eight more had had hemoptysis in connection with other phthisical symptoms. Subtracting the eight with bacilli from the thirty-two basic applicants above mentioned, there remain twenty-four with sputum not examined or reported negative. Some of these twenty-four probably had bacilli. Assuming that at least one-quarter, or six, out of this number would have shown them if repeated examinations of their sputum had been possible, we have fourteen tuberculous basic cases out of 6,769, or one in 483 applicants. These considerations lead Drs. Clapp and Lapham to conclude that tuberculous disease of the lungs begins at the base instead of at the apex in one case out of 500 or 600, roughly speaking. Although very few general practitioners, even among those who lead busy lives, treat more than this number, and therefore have little occasion to dread the danger of making a mistake from this cause, the careful diagnos-

tician will not forget that even if the apex is clear there may be a tuberculous process developing at the base of the lung.

## A PROBABLE MODE OF COMMUNICATION OF LEPROSY.

It is well known that the human tissues furnish a poor soil for the planting of the leper bacillus, however ineradicable the latter may be once it has become firmly rooted, as it were, in the skin or deeper structures. So true is this that many leprologists—trained observers and logical thinkers—have denied the contagiousness of the disease, and have sought with much ingenuity to explain the facts of the spread of leprosy or some other hypothesis than that of personal contact. The best known of these hypotheses, and the least accepted, is the celebrated fish theory of Hutchinson. According to this doctrine, leprosy is spread through the medium of fish, and as proof thereof is alleged the undoubted fact that the disease prevails more in maritime nations than among dwellers in the interior. The fact is, however, ignored that among many fish-eating peoples—whether fresh or salted fish, good fish or putrid fish—leprosy is unknown, while it is not unknown in certain places where fish forms an insignificant part of the dietary. An almost fatal objection to this theory is that the lepra bacillus has never been found in fish, either salt or fresh, and the only condition on which it can be accepted at all is that in some way a diet of sea food renders the human tissues vulnerable to the bacillary attack. The truth unquestionably is that leprosy is contagious, but contagious to a very slight degree. Mere contact with the specific germ, even of a raw surface, is insufficient; the contact must be prolonged and intimate, and every opportunity must be given the bacillus to become acclimated and to make the beginnings of growth undisturbed by outside influences.

It has been thought that possibly the disease is spread by means of the bites of fleas and other insects, but among the most plausible and satisfactory of the theories thus far suggested is that the itch mite is the inoculator. We do not know by whom this was first advanced, but Dr. Mugliston, Colonial Surgeon of Penang, has recently returned to the subject, adducing some rather strong testimony in support of the itch theory. Writing in the *Journal of Tropical Medicine* for July 15, 1905, he says that he had for many years noted the almost universal occurrence of itch in lepers, but until a few years ago looked on this only as one of the dirt conditions which might be expected in those who have little to look forward to in life, and so get careless of their surroundings. In connection with this he found that of 400 patients in the Pauper Hospital, twenty-five had itch. Later, as he began to recognize from various facts the communicability of the disease, it occurred to him that there was here an almost ideal method of inoculation, and he began to make inquiries on these lines. He found that of seventy-seven lepers, admitted from January 1 to May 31, 1905, forty-four had itch on admission, eleven more remembered having itch, and twenty-two could not remember. "When we take the life history of the *Acarus scabiei*," he adds, "we see that the way it burrows under the cuticle and remains in a position for a considerable time where the conditions are most favorable for the growth of the leprous bacilli with which it is covered, coming as it does from the part of the leper where the leprous bacilli are most numerous and vigorous, it is, I think, fair to assume that this is a possible way of communicating the disease."

As the lepra germ is a bacterial and not a protozoan parasite, it is improbable that an intermediate host is necessary for the development of an extra-human cycle. Therefore, it may be assumed that there is no specificity in the acarus mode of transmission, analogous to the rôle of the mosquito in malaria, but that the parasite acts merely as a very efficient inoculator because of its burrowing beneath the cuticle. This is doubtless only one, but perhaps the most effectual, of the various modes of transmission of the lepra bacillus.

## THE TREATMENT OF GONORRHEAL RHEUMATISM.

Gonorrheal rheumatism represents one of the most unwelcome complications in the domain of genito-urinary surgery. It is rebellious and uncertain rather than actually dangerous, but in order to appreciate its true character the fact should always be borne in mind that it is a systemic infection, the source of which is genitourinary. The infection may be, and probably is, a mixed one, but it bears no relation whatever to acute inflammatory or to muscular rheumatism. Just what rôle the gonococcus itself plays has not been fully decided, but it is assumed by many capable observers that the local inflammatory reaction which arises from its presence in the mucous membrane allows other germs to enter the system.

Eugene Fuller (*Annals of Surgery*, June, 1905) now brings forward the claim that gonorrheal rheumatism, so-called, can exist independently of the gonococcus, and that another agency may be present which can play the minor rôle assigned to the gonococcus of allowing other germs to enter the system from a genitourinary source. If so, then the common appellation is a misnomer.

The author of the paper referred to has made a special clinical study in order to determine whether the systemic infection in these cases entered from some specific source or from the general mucous surface. In the male this special focus he believes to be represented by a seminal vesiculitis. In fifteen cases of gonorrheal rheumatism, the only existing gonorrheal lesion in twelve was found in these organs. He then determined to remove this focus by operative means and thus to check the disease. This he did in four cases. Almost immediately the active symptoms of the trouble subsided, the joint movements being possible in from 24 to 48 hours, and the patients were up in two weeks.

These are striking results and apparently demonstrate the correctness as far as they go, of the author's theory. But the operation is a most difficult one, as the writer admits; it depends for its success largely on the sense of touch, since instrumental exposure of the organs is a dangerous procedure. Hitherto this region has been looked upon as quite inaccessible, and has, therefore, not been made the subject of any extended surgical interference. The success attained by Dr. Fuller in this field will undoubtedly stimulate others, and reports from these investigators will be awaited with interest.

### An Arctic Sanatorium.

It was announced early in the summer that an expedition was about to set sail for the Far North in search, not of the Pole, but of a cure for tuberculosis. The scheme progressed so far, at least, as the sending of an agent to Halifax to negotiate a charter for a vessel, but whether or not the party was organized and actually set sail for Greenland we are unable to say. The originator of the project was Dr. Sohon of Washington, who had been with Peary to Greenland, and was struck while there with the suitableness of the Arctic regions for the climatic treatment of tuberculosis. Writing on the subject in the *Washington Medical Annals,* he prefaces his argument with a statement of the generally admitted fact that the danger in a given case of pulmonary tuberculosis is, as a rule, not from the tubercle bacillus, but from the resulting mixed infection with pyogenic organisms. He believes that a summer spent in Omenak Fjord or Inglefield Gulf, in Greenland, would serve to establish a cure, or insure its accomplishment afterward, in nearly all cases in which the disease is not already completely overbalanced by septic complications. Four tuberculous patients who have gone to these places have been cured promptly and effectually. In other words, 100 per cent. in four cases have been cured. This evidence is not conclusive, and still this list includes all the known cases. The natives of Northern Greenland do not have tuberculosis, although there has been ample opportunity for infection from visiting whites. The greatest single drawback in the treatment of tuberculosis is the continual occurrence of unavoidable exacerbations of a catarrhal, pneumonic, or septic nature. Catarrhal conditions do not exist in the Arctic, and septic bacteria are not native. In the summer months all life is forced and stimulated; men and animals quickly recover from the winter anemias, and there is just such a forcing of vitality that consumptives especially need. Patients here would be removed from all influences which favor an extension of the disease or militate against an improvement. The never-setting sun unintermittently imparts energy; the atmosphere is dustless and sterile; there is entire freedom from danger of colds and other ills which cause setbacks. The sailing distance from New York to the extreme end of Baffin Bay is about half that between New York and Europe, and from the Northern railroad connection at Sydney, Nova Scotia, to the Arctic Circle the distance is approximately that between Boston and Key West. The waters are usually smooth. From the zeros of the mornings in May there is a constant rise of temperature until past the midday, or, as we should say, midsummer, and then a decline toward the evening in September. During most of this long day the temperature is above the freezing point, and rises in the forties and fifties after the snow melts in the spring and the rocks are sunwarmed. The usual fluctuations in any twenty-four hours do not equal the changes which occur in the single hour following our sunrise and sunset. The question of a proper food supply in the Far North is not radically different from the same question here. In that region the time required for a cure of tuberculosis is far shorter than in other climes, and so the summer voyage might suffice; at least it would lay a good foundation for a permanent cure. The writer urges that consideration be given to the dedication of a hospital ship for the purpose of carrying patients to the favored spots in the North which hold the complete essentials to a cure. Here is an opportunity, he thinks, for some philanthropist to give a sum sufficient to purchase and equip a vessel for an experimental voyage to the North.

### A Setback to Reciprocity in Medical Licensure.

Quite recently the New Jersey State Board of Medical Examiners decided that, for the future, they would not endorse the medical licenses issued by the New York State Board of Medical Examiners. For many years New York physicians have been able to practise medicine in New Jersey without having to undergo the ordeal of a further examination, but during this same period the New Jersey physicians have not been accorded similar privileges in this State. Hence the new decree on the part of New Jersey. Much as we may deplore the step as retrograde, and as antagonistic to general interstate reciprocity, New Jersey is not only acting within her undoubted legal rights, but has been driven to take this stand in self-defense and as necessary to maintain her self-respect. So far as we can see, the action of the New York Board has, for many years, been unreasonable. The New Jersey standards, both for preliminary or academic education and for medical education, are quite as high as those in force in this State. Her medical examination for the license to practise has one more paper than is set in New York; and as the examination questions on the remaining subjects are of about the same standard of difficulty in both States, New Jersey would seem to have the higher standard. Hence she has every right to expect that the courtesy which she has been in the habit of extending to New York should be reciprocated. It is up to the New York State Board to explain wherein the New Jersey requirements are in any way inferior to our own; for to the general medical public it is not apparent. Perhaps, however, some good may come out of this evil. Possibly the stand taken by New Jersey may cause such a careful comparison of and investigation into the licensing conditions existing in these two neighboring States as to bring about a mutual recognition, so that in the near future the holder of either license may practise in both States. We know of no two States wherein the conditions for medical practice are so similar, or where the reasons for reciprocity are more apparent. Here, then, is an opportunity for some medical diplomatist to show the advantages of arbitration, and for Peace to reap one more of her renowned victories.

## News of the Week.

**The Yellow Fever Situation.**—The mosquitos in New Orleans are being reduced in numbers by energetic and repeated attacks as never before in the history of the city. They are now so few that it is possible to sleep in comfort without a mosquito netting over the bed, Culex and Anopheles sharing the fatalities with Stegomyia, against which the attack is primarily directed. On Sunday last nearly every house was thoroughly fumigated to destroy the sleeping insects, and with cisterns screened and drains and pools oiled, there is little chance for reproduction on a large scale. There is a gradual abatement in the yellow fever epidemic, with an occasional temporary increase in the daily total of reported cases. The total number of cases up to and including Tuesday of this week was 1,503, with a total of 214 deaths. There will be a second general fumigation next Sunday, by which it is hoped to kill those few mosquitos that have escaped thus far. It is now believed that the fever can be got rid of in three weeks, in consequence of the drastic measures being taken. It is believed that the fever is under control, for the last two weeks of August are usually the worst weeks of the year in a yellow fever visitation. The deaths for

these weeks in August, 1855, were 1,500 a week, and in 1878 the mortality increased twelvefold between the first and last weeks of August. This year, however, the number of cases is diminishing during this period of normal exacerbation, and diminishing at the same time with, and doubtless in consequence of, the reduction in the number of mosquitos.

**Mortality Statistics of Immigrants in Transit.**—Acting Secretary Murray of the Department of Commerce and Labor has received a report from Collector Stranahan of New York, showing that during the past three fiscal years, ended June 30, 1905, from the ports of Europe 1,932,934 steerage passengers embarked for New York, of whom 423 died on the voyage, or about 22 deaths per 100,000 passengers. Allowing twelve days for the average voyage, the rate is equivalent to an annual death rate of about six and one-half (6.56) per 1,000. (The last Federal census shows the annual death rate per 1,000 in 1900, in New York City, was 20.4; in Washington, 22.8; and the lowest rate for large American cities, St. Paul, Minn., 9.7, and Portland, Ore., 9.5. The Federal census gave the death rate for Hungary at 30.3; Italy, 24.6; Germany, 22.8, and Norway, 16.5.) The highest monthly rate for the three years was January, the month of smallest travel, 38 deaths out of 87,260 in the steerage; the lowest rate, also 38 deaths, out of 256,838 steerage passengers, was May, one of the months of heaviest steerage travel to New York. From Northern Europe there were 242 deaths out of 1,351,221 steerage passengers; from Southern Europe, 181 deaths out of 581,713. Of the steerage passengers, 31,873 were babies under one year, and 116 more were born in the steerage, two mothers dying in childbirth; 126,993 were children over one and under eight years, and 1,774,068 passengers were over eight years. Under eight years 211 died; over eight years, 212. The census figures for 1900 give deaths under nine years in the United States, so exact comparison is not practicable. In the steerage, one and one-third died out of every 1,000 children under eight years. Only one steerage passenger out of nearly two millions died on shipboard from accident, and only one from yellow fever. Twenty-three committed suicide and seven disappeared (suicide, accident, or murder). The principal causes of death were heart failure, 75 (20 children); pneumonia, 64 (37 children); inflammation of bowels, 40 (all children but five); meningitis, 34 (14 children); convulsions, 28 (children); apoplexy, 17; alcoholism, 17; marasmus or weakness, 17 (13 children); tuberculosis, 16 (8 children); bronchitis, 15 (12 children); congestion, 10; five children died from scarlet fever and five from measles. The remaining forty-seven deaths were due to twenty-seven miscellaneous diseases.

**Mr. Christopher Heath,** F.R.C.S., Emeritus Professor of Clinical Surgery in University College, London, and a past-president of the Royal College of Surgeons of England, died on August 8. He was born in London in 1835, and was educated at King's College School, and at King's College and King's College Hospital, London. He served as a surgeon with the Baltic fleet during the Crimean War, in 1855. In 1856 he was appointed demonstrator of anatomy at Westminster Hospital, and six years later he was made lecturer on anatomy and assistant surgeon at the same hospital. In 1866 he was appointed assistant surgeon and teacher of operative surgery at University College Hospital, and in 1875 he became Holme professor of clinical surgery and full surgeon at the same hospital. In 1897 he delivered the course of Lane lectures at the Cooper Medical College, San Francisco, and for so doing was severely criticised by some of his enemies, of whom his polemical methods of argument had created not a few. He was the author of a number of works on surgical and anatomical subjects, the most widely known and popular of which was his "Practical Anatomy," first published in the '60s and reaching a ninth edition in 1902.

**Trouble Over Bellevue Bids.**—An application has been made to the Supreme Court for an injunction restraining the trustees of Bellevue Hospital from awarding the contract for Pavilions A and B of their new building. The contract was awarded to a firm of builders in this city, and the present action is brought by a taxpayer, who sets up in his complaint that the company securing the award, whose total bid was $645,526.95, is not the lowest bidder, as another contractor submitted a bid of $639,949.17. The bids were divided into several items, and the contract was awarded on the first two, on which the bids of the successful company were lower. The plaintiff asserts also that the award is illegal, because it was not made at the regular time and place of meeting of the board of trustees at Bellevue Hospital, but was made at a luncheon held at the Lawyers' Club.

**Gift of a Hospital to Utica.**—On St. Luke's Day, October 18, there will be opened in Utica, N. Y., a new St. Luke's Hospital, which is the gift to the city of Mr. and Mrs. Frederick T. Proctor. The building throughout is constructed of the best materials obtainable, and in every particular it will be furnished with the latest conveniences for taking care of the sick. The cost of the building, exclusive of the furnishings in wards, private rooms, and surgery, will not be far from $260,000. The building stands on high ground in the western part of the city, not far from the State Hospital for the Insane. Every modern device has been employed to make the building fireproof.

**Improving the Nassau Hospital.**—Mrs. William K. Vanderbilt, Jr., has stated that she will provide a children's ward, diet kitchen, dressing room, and more private rooms for the Nassau Hospital at this place. The hospital was established through the efforts of a number of prominent residents of Nassau County and the members of the Meadow Brook and Rockaway colonies, who some years ago gave a horse show and a series of races in order to raise money for it. Mrs. Clarence H. Mackay built and furnished the nurses' home, which adjoins the hospital, and also had a landscape gardener lay out the grounds and plant shrubbery and trees on the premises. Mrs. O. H. P. Belmont has established the Belmont Ward, where women patients are cared for without expense.

**Transferring Insane Patients.** — Fifty insane women patients from the Long Island State Hospital, at Flatbush, were taken a few days ago by the Lehigh Valley Railroad to the Willard State Hospital. These women form the first section of 400 patients who are to be moved within a few days, because there is no room for them in Flatbush. More will be taken to Willard, and another section will go to Rochester. The remainder will be cared for in the hospital at King's Park, L. I.

**Arrested for Striking Patients.**—Two of the attendants at the Morris Plains State Hospital for the Insane were recently arrested on the charge of slapping two of the patients in the face. The men pleaded guilty, but denied beating or otherwise maltreating the patients. No similar charge had been made against an attendant in this hospital for years, for the rule against striking a patient has always been strictly enforced here.

**Attempt to Burn a Hospital.**— A patient who was enraged because he had been shut up in a room alone

when drunk and abusive tried to set fire to St. Joseph's Hospital, in Paterson, N. J., a few days ago. He had been out of the hospital and returned in an intoxicated condition, and soon after being confined in a basement room was discovered applying lighted matches to his cot and the woodwork of the window. There were nearly three hundred inmates of the hospital—patients, sisters, nurses, and servants. The fire was quickly extinguished and the patient arrested on the charge of arson.

**The Norman Kerr Memorial Lectureship.**—Dr. T. D. Crothers of Hartford, Conn., superintendent of the Walnut Lodge Hospital, has accepted an invitation to deliver the first oration of the Norman Kerr Memorial Lectureship, at London, England, October 10, 1905. Dr. Kerr will be remembered as an eminent London physician, who made a special study of alcoholism and other drug disorders. He wrote several excellent books on this subject, including the article on Alcoholism and Drug Habits in the "Twentieth Century Practice," and was instrumental in securing the enactment of laws for the control of inebriates, and the promotion of hospitals for their care throughout Great Britain. He founded the British Society for the Study of Inebriety, in 1884, and this society and his friends have organized a memorial lectureship for yearly orations on his life and work. It is a very pleasant recognition of the progress of medical science in this country that an American physician should be invited to deliver the first lecture.

**Proceeding Against Abortionists in Indiana.**—A dispatch from Indianapolis says that in a recent decision one of the circuit judges took occasion to score the Indiana State Board of Medical Examiners for the methods stated to have been employed by some of its members to secure evidence against a physician who had been brought to trial for alleged criminal abortion. It was admitted in the argument for an injunction which the accused had applied for that the Board employed a woman to visit physicians and endeavor to get them to perform an illegal operation, and if they consented she would then file charges against them before the Board. She was accompanied by a man, and both of them, after filing a number of affidavits against reputable physicians, left the State. It was upon this evidence that the Board was proceeding against one of the accused when he filed suit for an injunction, which the court granted, thus preventing the Board from proceeding on the woman's testimony.

**Ambulance Collision.**—An ambulance of the Long Island College Hospital was struck by a trolley car last week at Columbia and Degraw Streets, and hurled some distance to the top of a pile of sewer pipes. The surgeon, Dr. John W. Goldsmith, and the driver were stunned, and had to be taken to the hospital in another ambulance, and a policeman, who was accompanyng them, was badly bruised, but the patient, a 'longshoreman, whose foot was hurt, escaped further injury.

**Philoprogenitiveness in Zion.**—First Apostle Dowie of Zion City has not only directed that hereafter all members of his church who marry must first have his written consent in order that the union may be recognized by the church, but has also issued a command that in future every couple married in Zion must increase the population by one child each year. Before marriage, however, even the chaste kiss is forbidden the engaged couple.

**Texas State Medical Department Short of Funds.**—The State Board of Health of Texas has exhausted its financial resources, and the various counties along the eastern border have been notified that they must bear the expenses of the quarantine against Louisiana themselves. The legislature cut down the allowance of the department and directed that no deficiency warrants should be issued, so that in case of an epidemic the State would be in a difficult position.

**Upper Peninsula (Mich.) Medical Association.**—At the recent annual meeting of this association, held at Houghton, the following officers were elected: *President,* Dr. I. A. Lawbaugh of Calumet; *First Vice-President,* D. E. S. Cruse of Iron Mountain; *Second Vice-President,* Dr. A. F. Snyder of Escanaba; *Secretary,* Dr. H. W. Long of Escanaba.

**Tennessee Medical College.**—At a recent meeting of the directors of this institution it was decided that the Tennessee Medical College should become the medical department of the Lincoln Memorial University of Cumberland Gap, Tenn., and that the new hospital now being built by the college should be known as the Lincoln Memorial Hospital.

**International Congress of Hydrology.**—The seventh meeting of the International Congress of Hydrology, Climatology, Geology, and Physical Therapeutics will be opened at Venice on October 10 under the presidency of Professor A. De Giovanni of the University of Padua. The general secretary is Dr. Fausto Oreffice, S. Stefano 2,803, Venice, to whom all communicantions should be addressed.

**Smallpox in Valparaiso.**—Smallpox is spreading with much rapidity through this city, and the new cases average 180 daily. The authorities are beginning to realize the necessity for universal vacination, but the supply of vaccine is limited. One hundred students from the Santiago Medical School have been sent to the city to serve as public vaccinators.

**Many Failures at State Examinations.**—Of fifty-eight applicants taking the examinations before the Oregon State Board of Medical Examiners in July, only about one-third passed.

**Hospital Records Demanded.**—In certain divorce proceedings at Wooster, Ohio, the Court has ordered the records of Christ's Hospital, Cincinnati, to be brought before the Court, to determine the condition of the defendant during her stay in the house. The attorneys for the hospital have refused to allow this. The Court threatens contempt proceedings if the records are not produced.

**Arrests for Milk Adulterations.**—Seventeen grocers and dairymen have been arrested in Cincinnati for milk adulteration. Some are charged with selling milk below standard and others with using formaldehyde as a preservative.

**The Fire at the University of Pennsylvania.**—The burning of Logan Hall, containing the anatomical and surgical departments of the medical school of the University of Pennsylvania, on August 14, did damage to the extent of $40,000. The greatest loss was entailed by the destruction of microscopes and other instruments used for histological purposes.

**Typhoid Fever in Columbus, Ohio.**—The health authorities of Columbus are investigating an outbreak of typhoid fever in one street, where members of a dozen families are down with the disease. The authorities are of the opinion that the disease is the result of drinking "tainted" milk, all those ill having used milk from one dairyman.

**Branch Hospital, Cincinnati.**—The Board of Public Service of Cincinnati have asked the Council of the city for a bond issue of $225,000 for the building of a new and larger pest house for contagious diseases and also a new consumptive pavilion.

**An International Congress for the Study of Radiology and Ionization** will be held at Liége, Belgium,

on September 12 to 14. The work of the Congress will be divided into two sections of the physical and the biological sciences. The program of the second section includes a study of the physiological properties of radioactivity, as well as its therapeutic and diagnostic uses. The Secretary-General of the Congress is Dr. J. Daniel, Rue de la Prévôté, 1, Brussels, Belgium.

**American Association of Railway Surgeons.**—The First meeting of this association will be held in Chicago, October, 2, 4, and 5, at the Northwestern University Building, under the presidency of Dr. John E. Owens, of Chicago. At a joint meeting of the American Academy of Railway Surgeons and the International Association of Railway Surgeons, held last year, these two associations dissolved, and then formed an association under the name of the "American Association of Railway Surgeons."

**Measles in Evanston.**—A correspondent writes that an item regarding the prevalence of measles at Evanston, near Chicago, published in the issue of August 12, was incorrect so far as present conditions are concerned. There were a number of cases of measles in that city in the spring and early summer, but at present there is very little sickness there of any kind.

**Obituary Notes.**—Dr. Samuel Sherburne died at Philadelphia on August 14, at the age of seventy-two years. He was a direct descendant of Henry Sherburne, who came to this country from England in 1631, and was the first settler at Portsmouth, N. H. Dr. Sherburne was born in Auburn, N. Y., and was graduated from Long Island College Hospital in 1862. He was an assistant surgeon in the United States Army during the Civil War.

Dr. Robert J. Clark died at Chestnut Level, Lancaster County, Pa., on August 18. He was graduated from the medical department of the University of Pennsylvania in the class of 1868.

Dr. A. C. Kemper of Cincinnati died August 17, at the age of seventy-three years. He was born July 11, 1832, in that city. He received his medical education in Dublin, Ireland. In the Civil War he served on the staff of General Halleck, with the rank of captain.

Dr. Frederick C. Hall died at Scranton, Pa., on August 14, as a result of septicemia, acquired in the course of an operation for appendicitis six years ago. He was graduated from the Medico-Chirurgical Hospital, Philadelphia, in the class of 1894.

Dr. Clarkson Crosby Schuyler died at Plattsburg, N. Y., August 16, aged fifty-five years. He was born in Troy, and was graduated from the Albany Medical College in the class of 1875. He was surgeon of the Troy Hospital for fourteen years. He was appointed State Forest Commissioner in 1893 by Governor Flower, serving two years. He was a member of many medical and other associations.

Dr. Charles H. Andrus died at Enfield, Mass., on August 13, at the age of eighty-one years. He was born in Windham, N. Y., and was graduated from the College of Physicians and Surgeons in this city in 1845. He practised in Poughkeepsie before the war. He was for four years a surgeon in the Civil War, serving in two New York regiments. From 1873 to 1893 he practised in Metuchen, N. J. Since then he had made his home with his son in Enfield.

Dr. Horace Laidlaw of San Francisco died on August 4, at the age of forty-six years. He was born in Milwaukee, and was graduated from the Medical Department of the University of California in 1880. He held the position of chief surgeon for the Oceanic Steamship Company for five years, and was also surgeon for the Spreckels at the Island of Maui, Hawaii, for a period of three years.

Dr. Frank A. Foster died in Boston August 9, after an operation for appendicitis, at the age of fifty-four years. He was born in Belmont, N. H., and was graduated in medicine from the University of Michigan in 1879. He practised for twenty-one years in Waltham, Mass., and later removed to Boston.

Dr. E. R. Weaver of Johnson Grove, Tenn., died at Chattanooga on August 4. He was a graduate of the Tennessee Medical College in the class of 1893.

Dr. Edward W. Doty died August 20, at Dover, N. J., at the age of forty-nine years. He was born in Newark, and, after engaging in various enterprises, began the study of medicine, being graduated in 1886 from the Long Island College Hospital. He practised for many years in Paterson, N. J.

## Correspondence.

### OUR LONDON LETTER.

(From Our Special Correspondent.)

BRITISH MEDICAL CONVENTION NOTES FROM LEICESTER—HOSPITALS AND RATES—LIVERPOOL TROPICAL WORK—NURSES.

London, August 4, 1905.

The Leicester meeting of the British Medical Association has joined its predecessors as something past, but here in London we are still talking of it when we meet those who attended. However, we do not meet them so frequently as you may suppose, for a considerable number started on their autumnal holiday from Leicester, and others who returned only delayed their trip for a day or two, and are now gone. Some of the points commented on may interest you. The reorganization of the society, which gave so much hope to many, is scarcely as satisfactory as it has been officially asserted to be. The "representative meetings" were diligently attended, and got through a great amount of business, but those not specially interested complain that the decisions taken were not all representative of general opinion, and at times much confusion prevailed. Much time was consumed in discussing the standing orders, which seemed as complex and difficult to alter as those of Parliament, which afford opposite parties such ground for delaying proceedings they dislike.

The proposal to apply for a royal charter was vigorously opposed on several grounds, but was eventually adopted after a vote by cards. The duties of delegates were so onerous in these "representative" meetings that they were unable to take the part they might desire in sections and general sessions. It was therefore proposed that they should in future be held in the week preceding the annual meeting. No decision was come to, as next year the annual meeting is to be held, as I told you, in Canada, and consequently the "representatives" will meet beforehand in England. For the 1907 meeting an invitation from Bradford was received with favor, but in accordance with custom, cannot be accepted until next year.

There was a great deal of talk about the annual report of the Council, and whether certain resolutions proposed could properly be discussed by the meeting, as they seemed to tend towards alterations of the by-laws, and would therefore be out of order. The report on contract practice prepared by the Medico-Political Committee, which is perhaps the best bit of work that committee has done, was discussed at great length in its various bearings, and eventually referred to the divisions, with a recommendation to hold an early special meeting of each "division" to consider separately each proposal made in the report.

Provident Dispensaries, Death Registration, the Midwives' Act, Medical Defense, and other similar subjects occupied no like attention.

As to questions of more general interest in connection with the meeting, of course the addresses in medicine and surgery occupy the first place. But any discussion or criticism of these would be out of place in view of the full reports you present to your readers.

A report on the coordination of the scientific work has been referred to the divisions—not without a *caveat* as to the amount of money being spent on scientific work and a plea for more being done for the general practitioners.

During the week the Council of the Association passed the following resolution: That Mr. Andrew Clark be instructed to inform His Majesty's Government that the British Medical Association cannot allocate any of its funds towards the support of any teaching appointment in a university or medical school.

At a largely attended meeting of the Council held on Friday, a comprehensive vote of thanks was passed to the Mayor and Corporation, and to every one concerned in making the affair a success, and a special vote of thanks to Mr. G. C. Franklin for his able and courteous presidency. This vote enumerated no less than twenty-six persons or societies. This day was also a full one from the more popular side, and the sections were somewhat depleted. One party journeyed to Belvoir Castle, the Liecestershire seat of the Rutland family.

In the afternoon Mr. Samuel Faire, J. P., and Mrs. Faire gave a garden party, and in the evening the Mayor and Mayoress of Leicester gave an evening fête in the Abbey Park, when there was a brilliant scene, the grounds being illuminated. This evening, also, the popular lecture was given by Prof. Stirling.

On Saturday a large party made an excursion to Buxton, with side excursions to Hope, Haddon Hall, and Chatsworth, and Makock. This, I am assured, was one of the best excursions, and those who went, to the number of about 150, were sumptuously entertained, though the hosts must have been somewhat disappointed, 300 having been expected. It seems too bad, and it is to be hoped such an occurrence will not be repeated.

Another party made a visit to Charnwood Forest, one of the most charming spots in Leicestershire.

During the week the annual meetings of the New Sydenham Society, the United Kingdom Police Surgeons' Association, and the Continental Anglo-American Medical Society were held.

The Dean of Canterbury, preaching in the Cathedral to the benefit clubs, put in a plea for hospitals. He said the progress of surgery had been so great that the time might come when all but the richest classes would resort to hospitals for treatment they could not have in their homes. Hence the support of these hospitals was a duty for all, and unless that duty was carried out voluntarily, compulsion would become necessary. There were those who would throw the support of hospitals on the rates, and that would be better than that they should not be supported at all. But there were overwhelming reasons which ought to save us from such a course.

At a meeting of the Liverpool Institute of Tropical Research, Sir A. Jones, who was elected chairman, emphasized the necessity for all interested in British commerce to encourage the application of scientific methods as much as their continental competitors are doing. The work of the institute would entail, as a main duty, the dispatch of research expeditions, and he guaranteed £1,000 a year for the next four years for this work. Mr. Lever guaranteed a similar amount, and other contributions were promised.

The report of the Select Committee on Nurses has been issued. It favors the registration of individual nurses and of training schools under a central body appointed by the state, and which should also license institutions and societies which supply nurses.

## Progress of Medical Science.

*Boston Medical and Surgical Journal, August* 17, 1905.

**A Case of Lymphatic Leukemia in a Child.**—John Lovett Morse reports such a case occurring in a child three and a half years old. This case was of interest in that it afforded an opportunity to study the development of the changes in the blood and lymph nodes during a considerable time, and that although it was most carefully studied, the correct diagnosis could only be made a comparatively short time before death It shows that the character of the blood changes may not develop to a degree sufficient to justify a positive diagnosis for many months. It also shows that the changes in the lymph nodes may be, not only at first but even for a considerable time, materially different from those which are usually considered to be typical of this disease. It is noteworthy that the characteristic changes in the blood and lymph nodes appeared at essentially the same time. The only inference that can be made from the histological study of these tissues at different stages of the disease is that lymphatic leukemia may have its origin in a malignant growth affecting the lymphoid tissues more or less generally, and that not until there is a secondary proliferation of the lymphoid cells do we get the typical tissue picture and blood condition which is characteristic of lymphatic leukemia. It suggests that leukemia pseudoleukemia, and malignant lymphoma cannot be separated as three distinct entities, and that they do not always differ characteristically in the histological structure of their lymphoid tissues; and that the microscopical sections in these cases will be often wrongly judged in the absence of complete clinical data as regards the distribution of the process and the examination of the blood. In short, this case emphasizes again our ignorance as to the development of the pathological changes in the diseases of the blood and lymph nodes.

*New York Medical Journal, August* 19, 1905.

**Some Remarks on the Epiphyses of the Long Bones, and Their Bearings on the Operation of Resection.**—John Knott says that the diaphysis of the clavicle is usually the first to appear in the skeleton, and the union of its solitary epiphysis is the last to take place. The peculiar tenuity of this unique epiphysis is such as to render the preservation of any portion, or even of its subjacent epiphyseal cartilage, in the operation of excision of the sternoclavicular articulation for well-pronounced disease, an utter impossibility. The upper epiphysis of the humerus is limited by an epiphyseal cartilage which forms a small segment of a hollow sphere, whose convexity is upward, and whose circumferential margin occupies a horizontal plane when the limb is held in the vertical position. On the under side it approaches the obliquely placed articular cartilage, and it is here only that its presence need be remembered in connection with the operation of excision of the joint. The lower epiphysis of the humerus has such an arrangement of ossific centers, in connection with epiphyseal fractures, that such an accident produces but an extremely slight diminution of the prominence of the external condyle in any case, while it removes the small tip of the internal epicondyle from the shaft or not, according to whether it takes place before or after the separation of the ossific center from the rest of the epiphyseal plate. In short, in the occurrence of the epiphyseal fracture of the lower end of the humerus the lower fragment carries with it but a minute portion of the external epicondyle, while it removes either the small projecting tip of the internal epicondyle, or more probably none at all, according to the age of the patient. The extreme thinness of the stratum between the articular cartilage and the epiphyseal cartilage in this position renders it, of course, absolutely impossible to remove more than a thin articular slice from the lower end of the humerus without removal of the epiphyseal cartilage itself and consequent arrest of longitudinal growth at the lower end of the bone. The upper end of the ulna presents an epiphysis of considerable vertical extension. It also presents a supplemental epiphysis placed over the main one, occupying exactly the position of the insertion of the triceps tendon, and presenting the general appearance of a liliputian patella, thus introducing a hitherto unrecognized item of homology between the knee and elbow joints. The upper epiphysis of the radius is of moderate thickness, and limited by a horizontal epiphyseal cartilage. The epiphysis of the lower end of the femur is a very large one, and its ossific center is generally the only one to form within an epiphysis during intrauterine life; as it normally appears within the last week or two of that important period of existence, its presence is the most reliable item of evidence of the maturity of the fetus which can be procured in a doubtful or disputed case. The union of this epiphysis with the shaft of the femur is the latest of any in the bones of the limb, and, as growth proceeds while the epiphyseal cartilage remains unossified, the future gigantism or dwarfism of the otherwise normal individual depends more upon the behavior of the epiphysis of the lower end of the femur than upon all the other segments of the human skeleton. The upper epiphysis of the tibia forms a comparatively thin lamina, so that it would not be possible to save a portion in excision of the knee joint, if this part of the bone was at all diseased. The epiphysis of the lower end of the fibula is noted for its breach of the osteological commandment—to the effect that "that epiphysis of a long bone toward which the nutrient artery is directed shall be the last to ossify, and the first to unite with the diaphysis." The lower epiphysis of the lower end of the fibula breaks the first part of this; it ossifies first.

**The Employment of the Dry Cups in the Treatment of Herpes Zoster.**—Medwin Leale desires especially to emphasize the fact that the careful and scientific application of dry cups has proved of great value in his hands in the treatment of herpes zoster, shortening the disease and ameliorating the symptoms. He gives a diagram to show the localization of the sensory functions of the segments of the spinal cord as laid down by M. Allen Starr, and which serves as a guide in the application of these cups. The dry cupping is done just to the affected side of the spinous processes of the vertebræ over the area determined, several cups being applied and allowed to remain long enough to insure their maximum suction power. Then a few cups are applied to the location of the emergence and over the course of the nerve or nerves involved, being guided by the seat of the pain and hyperesthesia and by

the location of the eruption. He finds it best to repeat the cupping once every twenty-four hours.

**A New Method of Extirpating the Internal Saphenous and Similar Veins in Varicose Conditions.**—W. L. Keller thus describes the operation: The vessel to be removed is exposed by a short incision near the femoral opening of the fascia lata (if the internal saphenous), and is dissected free from its sheath for about one inch, and ligated as high up as possible. The lower end of the vein is exposed and treated in a similar manner. The vein is now cut below the proximal end and above the distal end, thus leaving the section to be removed free and ready for removal. The upper end of the section to be removed is now split for about three-quarters of an inch on its anterior wall. A strong ligature is then tied to the upper end of the vein, care being taken not to include more tissue in the ligature than will pass through the lumen of the vessel. A wire loop or probe is then passed through the lumen of the vessel from the lower opening and the ligature is threaded through the eye of the loop or probe; the probe is then withdrawn and the ligature brought out upon the surface at the point where the probe entered. Gentle traction is now made upon the ligature, the edges of the vein being inverted into its own lumen by an assistant. Traction is continued until the vein is completely extirpated by being turned inside out and withdrawn from its sheath.

*Medical News, August* 19, 1905.

**The Impossibility of Differentiating So-called Paratyphoid from Typhoid Fever Except by a Bacteriological Examination of the Blood.**—Warren Coleman says that if cases of infection by intermediate members of the typhoid-colon group of bacilli, when pursuing a typhoidal course, cannot be distinguished from typhoid fever without the aid of laboratory methods, the introduction of the term "paratyphoid fever" is clearly unjustifiable, and he attempts to prove that so-called paratyphoid and typhoid are identical clinically, and that they can be differentiated only by the recovery of the bacillus concerned from the blood. In 1902 he took the ground that paratyphoid infections did not constitute a clinical entity, and that there was as great diversity among the different types of typhoid fever as between typhoid fever and paratyphoid infections, and that the idea of the specificity of typhoid fever should be abandoned and that the scope of its etiology should be broadened to include *Bacillus alkaligenes fæcalis, B. typhosus, B. paratyphosus,* and certain others of the paracolon group. He at present sees no reason for modifying that view. His conception of the subject follows with a brief review of the bacilli constituting the typhoid-colon group. He concluded that (1) paratyphoid infections cannot be distinguished from typhoid fever except by the recovery from the blood of the bacillus concerned and its proper identification; (2) that the present state of our knowledge makes it advisable to consider typhoid fever clinically as a disease which may be caused by several members of the typhoid-colon group of bacilli; (3) that the term "paratyphoid fever" is not only unnecessary but misleading. In further substantiation of his position he calls attention to the fact that the term "paratyphoid fever" has been discredited in Germany, Belgium and Russia.

**Suprapubic Prostatectomy.**—A. I. McKinnon says the constant use of the catheter is invariably followed by dangerous complications and not infrequently periods of complete retention, with all the dangers and discomforts of distention, supervene. This symptom he believes to be an absolute indication for radical procedure. Too often mere suprapubic aspiration is selected as the best means of securing relief in this condition, and he wishes to protest against such procedure, as tapping an infected bladder with thickened walls is liable to cause a leak at point of puncture. The judicious plan of treatment is to perform suprapubic cystotomy, and this should be done at once and drainage of the bladder instituted. Various methods have been described or devised which narrow down to those (1) which are partial with knife or cautery, palliative in their intent, and not to be recommended because they have all the disadvantages and none of the advantages of the complete operation; and (2) complete enucleation of the gland, which is the operation to be recommended in every case of hypertrophy with symptoms, an operation which he describes, calling especial attention to the distending the bladder with a large amount of iodoform gauze, after the manner of a Mikulitz drain. This packing prevents hemorrhage, ensures antisepsis, and drains away the urine as soon as it accumulates. It also prevents the ammoniacal odor of the urine. The points emphasized are: 1. Suprapubic cystotomy under local anesthesia instead of aspiration as an emergency measure in cases of complete retention from enlarged prostate. 2. The simplicity and freedom from complications and sequelæ of the operation when performed by the suprapubic method. 3. The virtue of packing the bladder with iodoform gauze after the method pointed out.

**Prevention and Treatment of Puerperal Sepsis.**—L. C. Fischer emphasizes the following points: The careful preparation of the bed and woman before the birth of the child, with especial attention to the hands of the physician. The examination of the placenta and membranes. After birth of the child examination of the perineum for tears, and if they are present repair them at once. In case there is a rise of temperature start at once with treatment. The importance of making careful digital examination, the use of the dull irrigating curette early, where the temperature is not reduced by douches. The importance of the normal salt solution to dilute the toxins, and to aid absorption. The preference of tube over gauze drainage in these cases; the absolute avoidance of gauze in the uterus after curetting. The importance of opening and draining the abscesses as they form in the pelvis or any pelvic organ.

*American Medicine, August* 19, 1905.

**The Matas Operation for the Cure of Aneurysm.**—John H. Gibbon says this operation consists in controlling the flow of blood in the diseased vessel by compression; free incision of the sac from end to end; evacuation of its contents; closure by suture of the arterial openings in it; and then obliteration of the sac by plication and infolding of the skin. In the case of a sacciform aneurysm but one opening requires closure, and when this is done the caliber of the vessel is reestablished. In the fusiform aneurysm there are two courses open to the operator—one of closure of the two openings of the artery into the sac, and of any collaterals which might originate within the sac, and then the entire obliteration of the sac by continuous rows of sutures; or, he may follow the suggestion of Matas of reconstructing the arterial caliber by utilizing a portion of the aneurysmal sac and suturing it over a catheter which is withdrawn before the last sutures are tied. Even when it is impossible to reestablish the vessel itself, this procedure of Matas possesses great advantages. The aneurysmal sac is as completely done away with is if it were extirpated, and there is less interference with collateral circulation than by any of the various methods of ligation. The operation of Matas is applicable to all aneurysms in which there is a distinct sac, and in which the cardiac end of the main vessel can be thoroughly controlled. The case reported is that of a negro, aged 31, who suffered from a large popliteal aneurysm. The sac was laid freely open and the arterial openings sutured. The sac was then obliterated by repeated rows of plicating sutures. The wound was closed without drainage. Suppuration took place, but the patient made a complete recovery after superficial drainage was established. Some months after the operation there was no evidence of a recurrence. Suppuration has occurred in a number of cases reported, but does not in any way seem to interfere with the cure. Dr. Gibbon says that in another case he would introduce a superficial drain.

**Treatment of Chancre and Chancroid.**—David E. Wheeler, in discussing this subject, classifies venerial ulcer into (1) simple uncomplicated ulcer, treatment consisting of frequent irrigation and wet dressings. (2) Ulcer complicated by phimosis. If attempts at reducing the phimosis fail, lateral incisions and secondary circumcision should be done; primary circumcision is contraindicated. (3) Ulcer complicated by paraphimosis. If seen early, immediate reduction is imperative; if not seen until sloughing has relieved the strangulation, expectant treatment should be instituted. (4) Phagadenic ulcer. Irrigation should be done every two hours, day and night, and iodoform used Escharotics are positively contraindicated.

**The Elimination of Endogenous Uric Acid in a Case of Chronic Gout.**—A. T. Laird reports two series of tests made while the patient was on a special diet. Together they cover about five weeks and include two periods during which the symptoms showed acute exacerbations. In the first series the diet was strictly "purin-free" after the sixth day and practically so (vegetable diet) from the start. During the second series it was "purin-free" throughout. Estimation was made of the daily excretion of uric acid and of phosphoric acid. The acidity of the urin was also determined and a series of leucocyte counts were made. The elimination of "endogenous" uric acid was found to be below the amount considered normal by Burian and Schur and others. The values found were lower than those recorded by Kaufmann and Mohr and in a similar study of five cases of chronic gout. The phosphoric acid elimination was also low, but no constant parallelism was found between it and the uric acid excretion. The leucocyte counts were within normal limits and did not vary with the uric acid excretions. No digestive leucocytosis was noted. The acidity was at all times low. The highest values for acidity were those obtained during an acute exacerbation of symptoms.

**Treatment of Infected Otitis Media.**—J. G. Huizinga concludes that chronic suppurative otitis media is an infectious condition of the entire auditory tract. It is impossible to

disinfect this tract in its entire length simply by means of syringing as ordinarily performed. No cure can be expected unless this tract can be made surgically clean by forcing the antiseptic fluids through from end to end of the entire tract. It is necessary to have a large opening in the drum and a thoroughly dilated condition of the eustachian tube, both for the purpose of drainage and of efficient cleansing. It is important to have a continuous current of antiseptic vapor passed through a eustachian catheter into the eustachian tube both for cleansing and dilating purposes. This is best accomplished by connecting a vaporizer containing iodine, menthol, and creosote in oil, with a large air tank, having the air compressed up to 30 pounds. The valves are opened and a continuous current of antiseptic air is forced through the catheter and into the eustachian tube until the pressure goes down to 20 pounds; this requires several minutes. By this method thorough and complete dilatation and the cleansing and disinfection from the use of the antiseptic solution are accomplished and the danger of driving infected material that may be present in the eustachian tube into the deeper parts of the middle ear is avoided. It is necessary to treat the parts sufficiently often ot maintain as nearly as possible a condition of antisepsis. No treatment can be considered thoroughly that does not recognize the relation existing between pathological conditions in the nose and nasopharynx and the ear.

**Enterotoxismus.**—Harris A. Houghton calls attention to the fact that the word "autointoxication" as is now used has many different meanings, leading to considerable confusion and inaccuracy. According to the dictionary definitions and common usage, the word may indicate the toxemia following cellular malactivity, as lithemia, the acidoses of diabetes and allied conditions, and secondly indicate intoxication of enteric origin, which has its chief clinical manifestation in an increase of the urinary ethereal sulphates. These are two distinct conditions and probably of different etiology. Houghton suggests that autointoxication of enteric origin be designated by another name, viz., "enterotoxismus," and gives the following definiton—that morbid condition characterized by the absorption of substances from the gastro-intestinal tract which are toxic by virtue of their quantity or quality and which are produced therein by the disintegration of food-stuffs through the perverted or prolonged action of enzymes or the activity of entophytes.

*Journal of the American Medical Association, August 19, 1905.*

**The Medical Relations of Mouth Conditions.**—L. Duncan Bulkley remarks that in the course of his dermatological practice, he has had frequent occasion to note oral conditions, and has become much interested in the subject. The importance of proper mastication is emphasized, and incidentally he emphasizes the very great advantage of thorough mastication in seasickness. The remarkable vitality of the oral tissues is also noted, and is explained in part by the character of the saliva, which is affected to a very large extent by various bodily conditions. We must look, therefore, to the constitutional condition of the individual as modifying the saliva, or soil in which the microorganisms of the mouth are bathed, for the cause of many of the disorders that may affect the parts. Any diminution of vital resistance has its effect on the structures of the mouth as elsewhere. Dyspepsia is a fertile source of mouth trouble, as constantly observed in the case of so-called "canker sores," and dental decay may follow and vary with the condition of the stomach. Bulkley has also often noticed the effects on the gums and teeth of the acid state associated with gout, rheumatism, and rheumatoid arthritis, and has seen Rigg's disease markedly benefited by a purely antacid treatment. He asks why should not the dentists more often seek the aid of a physician in some of these cases. Syphilis, of course, is the most frequent cause of buccal lesions, and it is very important that dentists should be able to recognize the effects of the disease in this location. This is a matter on which he had before addressed the dental profession, and he repeats his warning here. Aside from canker sores due to disordered digestion, leucoplakia is probably the next most frequent diseased condition found in the mouth, usually in men and principally in those who have used tobacco. It is comparatively harmless, though it may be the starting point of epithelioma if injudiciously treated, but it is often perplexing on account of its resemblance to the lesions of syphilis, and many a patient has been long under needless specific treatment because of this innocent local affection. Epithelioma is the most important disease of the mouth, as elsewhere, and here the dentist can be of service in many ways. In many cases, it is started and kept up by irritation by ragged, decayed teeth or by amalgam fillings, and these should be sedulously looked to and corrected. With any suspicion of epitheliomatous conditions, competent medical counsel should be advised, and any meddlesome procedures avoided. Lupus sometimes affects the mouth, but it is so rare in this country as hardly to need consideration. Localized tuberculosis, however, is not so rare, and is often mistaken for syphilis. Patients should be warned against neglecting this. Lastly, Bulkley mentions the reflex disorders due to bad or to imperfect teeth, and the frequent need of the dentist's assistance in such cases, also the derangements of digestion and nutrition due to imperfect oral antisepsis.

**Medicine in the Philippines.**—J. R. McDill describes the condition of medical affairs in the Philippines. He does not believe that the climate is necessarily fatal or unduly enervating to Americans, especially as the Benquet Sanatorium will soon be available. He describes the work of the Board of Health and the laboratory facilities which it affords, and speaks especially of the need of general and special hospitals. The history of the medical organizations since the American occupation and the status of medical education in the islands are also noted. It appears that as yet there has been no marked affiliation between the native and American physicians, and McDill thinks this will hardly occur till a new generation, educated in English and in modern methods, has arisen. At present the ratio of physicians to population outside the city of Manila is 1 to 51,786, or one physician to each 430 square miles, and to supply the medical and sanitary needs of the country 2,000 or 3,000 native physicians and sanitarians should be educated there during the next twenty years. There is a unique opportunity for the establishment of the ideal university and affiliated professional schools in the Philippines, and there will be no lack of earnest, capable students. The medical profession is waiting for some one to contribute for the establishment of a Philippine university and medical school.

**Urinary Diagnosis.**—Benjamin Tenney describes the symptoms and diagnosis of urinary disorders at considerable length. He finds that while occasionally there may be reflex symptoms due to some outside condition, when the three symptoms, localized pain, altered function and hematuria, are met togther, little doubt exists of the presence of some surgical condition in the urinary tract. With only two of these present, surgical disorders of the urinary tract should be excluded before attention is directed to other organs, or the patient left to nature somewhat upset by the various so-called urinary antiseptics and sedatives. Tumor, tenderness, and residual urine, he says, do not require complicated apparatus for their recognition, and their presence or absence can be determined by any physician who will take the trouble to examine his patients carefully. These preliminary points are simple, usually sufficient for a correct diagnosis and always trustworthy in indicating the urinary tract as a source of trouble. A complete and correct diagnosis of the exact local conditions, however, as a preliminary to operation, calls for as much attention and accurate observation as anything else in surgery.

**Lateral Tendon Insertion Displacement for Strabismus.**—E. Jackson describes the mechanism of the action of the tendons of the recti on the movements of the eyeball and advocates the operation of partial tenotomy to modify the direction of their pull in cases of strabismus. In partial tenotomy, the division of the tendon begins at one edge of the insertion and extends beyond the middle. To have very much effect almost the whole breadth of the insertion should be divided, but in any case sufficient tissue should be left to keep the uncut margin of the tendon perfectly firm. In making such a partial division, therefore, the whole tendon should be raised on the strabismus hook and drawn round so that the operator can see just how far the firm tissue of the tendon extends. Jackson has practised this operation on the superior and internal recti tendons chiefly for excessive convergence. He gives his method in detail, and describes the operation of extended tenotomy consisting of the division of the internal rectus with lateral displacement of the superior and inferior recti, which he finds simple and effective in some cases. No unfavorable results have been encountered, and no protrusion of the eyeball, which sometimes occurs after imperfectly performed tenotomies.

**Sympathetic Inflammation Following Panophthalmitis.**—W. Zentmayer calls attention to the fact that until a comparatively recent period it had been held that eyes which had been the seat of purulent panophthalmitis did not excite sympathetic inflammation. He enumerates the authors who have reported cases of sympathetic inflammation from this cause, and briefly analyzes the fifteen cases that he has found recorded. He also reports a case of his own personal observation with pathological findings, and concludes that, while rare, they may occur, and that in such cases the microscopic changes are analogous to those found in other exciting eyes. Most generally the preceding clinical picture is that of a mild form of purulent uveitis. Only after the virulent form of panophthalmitis should the resultant shrunken globe be considered harmless. When the panophthalmitis has been of a low grade or whereas a result of treatment, the inflammation has not been of a virulent type,

the eye should be considered a dangerous one, and should be enucleated. It is possible that the original injury or disease may be the responsible exciting cause in some cases. Whether the histologic findings are to be considered in most panophthalmitic eyes as a terminal stage of the inflammation or as the evidence of a mixed infection is undecided. Zentmayer gives several reasons why panophthalmitic eyes may be harmless. Many of the noxious germs are extruded with the pus, and those retained become inactive through the enormous suppuration which, by blocking the posterior lymph spaces, also serves to prevent the migration of the microorganisms. Finally, he states, the panophthalmitis may have been induced by organisms incapable of producing sympathetic inflammation.

*The Lancet, August* 12, 1905.

**Two Cases of Death After Operation for Frontal Sinusitis.**—St. Clair Thomson draws the following conclusions from these two cases: 1. In cases of multisinusitis it is well to drain the maxillary cavity some time before the frontal is operated upon. Both cavities may be operated on at the same time; but if only one sinus is operated on at a time it should be the frontal sinus, the lower cavity being drained until it can be opened. 2. In spite of free opening of the frontal sinus, the establishment of a large communication with the nose and the avoidance of closure of the external wound, a slow infection of the bone may take place, leading ultimately to infection of the meninges. This may even be started in suppurating cavities on the *opposite* side to the one operated on. 3. The local condition of the wound, as well as the pulse, temperature, and feelings of the patient may fail to indicate the onset of mischief. After one to three weeks this is revealed by headache, pain, tenderness, and puffy swelling on the forehead or around the eyes. 4. When septic osteomyelitis has started the most vigorous measures may fail to arrest it. It may last one and a half years before terminating fatally. 5. The chief danger appears to lie in the ethmoidal labyrinth, owing to its anatomical irregularities and to the difficulty of treating them satisfactorily. 6. Up to the present the operation which best meets these difficulties is that of Killian. In many cases a preliminary endonasal operation on the ethmoid is advantageous.

**A Case of Parotitis Due to the Pneumococcus.**—S. Hastings and W. T. Hillier report the case of a man, aged fifty-five, with a swelling of the right side of the face, which had been accompanied with a continuous but not severe aching pain in the region of the swelling, and it hurt him when he opened his mouth. When the patient opened the mouth the septic condition of that cavity became evident. The teeth were much decayed, and there was a certain amount of pyorrhea, with retraction of the gums. Later, the left side became involved. Five days after first coming under observation all swelling and pain had disappeared. The treatment had been a very simple one. A nearly pure culture of a diplococcus was obtained in forty-eight hours' incubation at 37° C. from the saliva. It retained the stain when treated by Gram's method, and it possessed a capsule. There appeared to be no reason to doubt that the parotid swelling was inflammatory in nature, and they attributed it to the diplococcus, which was obtained in pure culture in the secretion of the gland. This organism they recognized as pneumococcus, but of a strain possessing but little virulence.

**Aspiration in Diseases of the Ear and Nose.**—M. R. Sondermann says that irrigation for the removal of pus is impossible in cases of acute suppurative inflammation of the middle ear and of the mastoid process as long as there only exists a small opening in the membrana tympani. In the same way, blowing through the eustachian tube and through the external meatus to evacuate pus has proven to be of doubtful success only. Greater advantage can be derived from the aspiration method, although until now it has been but rarely applied in the therapeutics of diseases of the ear. An illustration is shown which not only hermetically closes the external meatus, but also covers in the whole ear, including the auricle, thus overcoming many difficulties. It consists of a hollow mask, open at one side and surrounded by a hollow ring of hardened rubber, and by means of an elastic tube it is connected with the suction ball. The latter, as well as the elastic tube, possesses a valve by which the air can only pass outwards after the suction ball has been compressed. As the mask is of triangular shape, it can also be applied to the nose. In cases of acute suppuration a slight aspiration will be found sufficient in order to evacuate the pus from the middle ear, and even from the cells of the mastoid process into the external meatus. In cases of chronic empyema a stronger suction ball may be used, and especially when the ossicles and membrana tympani are missing. When the apparatus is applied to the nose it is necessary to effect a thorough closure of the throat as well. There are two possible ways of closing the nose towards the throat: (1) By making the patient pronounce the vowels, and especially i (long German i equals English ee), and (2) by swallowing. The former method should first be tried. The aspiration effect is directly noticeable by a strong suction feeling. The mucous membrane becomes red, and is covered with a thin layer of mucus. The pain is alleviated when this treatment is employed, and the results hitherto obtained by him justify the hope that in many cases a long, lasting improvement will be sure to be effected.

**Delayed Chloroform Poisoning.**—E. W. Scott Carmichael and James M. Beattie report this case. It was markedly noticeable in this case that chloroform produced pathological changes indirectly in the tissues by destroying the red blood corpuscles with increasing anemia. Thirst was a marked symptom. The character of the vomit differed from that of most recorded cases. Six hours before death she vomited some coffee-ground material, probably the result of repeated retching. Delirium was absent. The clinical picture was similar to the ones already described by Stiles and McDonald, Guthrie, and others. There was no sign of jaundice throughout. Extreme pallor was very marked. The pathological appearances were in the main similar to those of the case described by Stiles and McDonald. The main objections to the view that the clinical symptoms and the pathological appearances in these cases were due primarily to chloroform poisoning are founded on the facts that similar symptoms and similar pathological changes are found in patients who die as the result of fat embolism and in those who are poisoned by chemical agents or by septic products. Each of these are dealt with in turn.

**A Case of Sacculated Aneurysm of the Abdominal Aorta, Treated by the Introduction of Silver Wire and the Passage of the Constant Current.**—Cornelius A. Griffiths reports this case, and gives a description of a simple method of introducing the wire and insulating the current. The aneurysm presented immediately below the diaphragm and above the lesser curvature of the stomach. The placing of a temporary ligature around the aorta on the proximal side of the tumor was not practical, as the sac left no room between its walls and the diaphragm. A spot devoid of large vessels was selected and a small circle inclosed in a purse-string suture, and through the center of this a fine long trocar and canula were thrust well into the sac. The trocar was withdrawn, and through the canula was introduced a vulcanite canula for insulating purposes. Next, some fine silver wire was introduced into the sac through the double canula. After a foot or so of the wire was in it was cut off flush with the canula and pushed home with a ramrod. Some more wire was then pushed through and connected with the negative terminal of a constant current battery, the circuit being completed through the patient by means of an electrode placed on the thorax. A current of from fifteen to twenty-five milliampères was given for fifteen minutes. The wire was then pushed home with the ramrod, the cannulæ were withdrawn, the purse-string suture was tied, and the abdomen closed. The rapidly fatal termination in this case was favored by the interference with the functions of the stomach, which was stretched around the left and lower borders of the aneurysm.

*British Medical Journal, August* 12, 1905.

**The Behavior of Leucocytes in Malignant Growths.**—J. B. Farmer, J. E. S. Moore, and C. E. Walker have combined their observations of the peculiar behavior of leucocytes in very early carcinomata of different parts of the body. These phenomena do not occur in older growths, in metastases, or in grafts. In three cases observed these phenomena seem to relate to the change of normal tissue cells into cancerous elements. Where tissues are becoming cancerous there is a marked leucocyte activity, and the cells of the part may contain leucocytic bodies in their cytoplasm. In a small rectal cancer there was found a distinct transition zone between normal and cancerous elements, around the tumor; within the thickness of a few cells you could pass from normal mucous cells to decidedly malignant ones. The authors conclude that the growth did not originate from a single cell, but by the direct conversion of a great many mucous elements. Just within this zone the leucocytes were crowded, and many epithelial cells contained leucocytes. They were not seen in the healthy tissue, nor are they found in ordinary inflammations. Neither cell seemed to be harmed or destroyed, and in cells that were undergoing division the leucocytes were also dividing. A mixture of the chromosome from the leucocytes and the tissue cell was distributed between the nuclei of the daughter cells. This union does not correspond with the union between the definite cancer cells of neoplastic growths.

**Dysentery: Its Causation, Varieties, and Treatment on Active Service.**—E. Llewellyn Jenkins says that dysentery is a disease that is associated with the mobilization of a

large body of men. It is believed that there are two or more distinct varieties of the disease produced by different microorganisms; these are the bacillus coli dysentericus, a virulent form of streptococcus, and certain innocent organisms that, in mixed infection with the other two, increase their virulence. The chief predisposing causes are overcrowding, with the attendant violations of the laws of hygiene; scarcity and poor quality of food; anything that reduces the vitality, such as alternations of heat and cold, bodily exhaustion, lying on damp ground, mental anxiety. The direct cause of infection is pollution of soil and water by fecal material. It is doubtful if the disease is carried directly from man to man, but dust and flies easily convey the germs from exposed fecal matter to food and water. Heat is certainly a factor in its production. The treatment is primarily preventive; disinfection of all stools from dysenteric cases, and their cremation or deep burial; careful guarding of the water supply of all camps, and boiling all drinking water; protection of foodstuffs from flies; prevention of all conditions that reduce the vital force. Rest and diet are primary therapeutic measures. All movement should be avoided. Three or four pints of fresh milk per twenty-four hours is the best food, in small amounts at frequent intervals. Condensed milk, beef tea, and chicken soup may also be used. Food should be given warm, to lessen peristalsis. The best means of relieving pain and tenesmus is the starch and opium enema and the application of hot flannels to the abdomen, steeped in opium liniment, and hot bottles to the feet, with plenty of blankets when the weather is cold. The bowel must be cleansed by gently acting aperients; one-half ounce of sulphate of soda every hour gives good results. Ipecac is useful, given in thirty-grain doses of powder on an empty stomach every four or six hours until the stools become yellow and less shiny. When the acute stage has passed supportive treatment is in order; eggs and chopped raw meat may be given, and later, tonics and a sea voyage.

N. Faichnie divides dysentery into three varieties: amebic, sporadic due to mechanical irritation, and epidemic or bacillary. The last is the one usually seen in armies in the field. It arises from the dysenteric and paradysenteric bacilli and the bacillus coli. It is contracted from impure water, dust, flies, lack of cleanliness of hands and clothes, or infection from latrines. The preventive treatment includes immediate reports of sickness, isolation of all cases of the disease, disinfection of stools, covering of latrines, and disinfection of clothes and person after convalescence. Acute cases require rest, with sulphate of soda or magnesia, given concentrated and lukewarm. When there is no longer blood or mucus in the stools, perchloride of mercury should be given with tincture of chloroform and morphine every few hours. Starch and opium enemata relieve pain. In chronic cases castor oil is substituted for the other laxatives, followed by bismuth and opium. Flushing of the colon with bicarbonate of soda, sixty grains to the pint, followed by two or three pints of solution of tincture of iodine, twice a day gives good results in chronic cases. The author prefers whey and albumin water to milk as a diet. Canned milk is apt to produce nausea and accumulation in the bowels of undigested curds. The whey may be made from condensed milk by the use of alum, twenty to forty grains to the pint. Digitalis is to be preferred to alcohol as a heart stimulant.

**Warts and Corns.**—Arthur Evershed says that the best and most effective remedy for warts and corns is sea water. When sea bathing is not possible, warm foot baths of sea salt will take its place. If used daily, at the end of a fortnight the corns will peel off. Warts are treated by soaking the hands in warm sea water twice a day for ten minutes. Cauliflower warts on the scalp yield to a compress of sea water left on all night each night for two weeks.

**A Nasal Calculus.**—F. W. Taylor gives an account of a case of chronic pharyngitis, without discharge from the nose, in which examination showed the inferior meatus of the left nostril to contain a large bismuth-colored calculus, forming a mould of the cavity. It was removed after crusting, and a small head was found in the center. A projecting spur from the septum had held the head in place from its entrance into the nostril thirty-five years before.

*Berliner klinische Wochenschrift, July* 31, 1905.

**The Path of the Tubercle Bacilli from the Mouth to the Lungs.**—Beitzke says that three different paths have been named by various observers as being the route followed by the tubercle bacillus in its way from mouth to lung. These are: (1) Cervical lymphnodes, lymphatic duct, superior vena cava, heart, lung. (2) Cervical lymphnodes, supraclavicular glands, pleural dome, pulmonary apex. (3) Cervical glands, bronchial glands, lung. The author's experiments showed him that the glands draining the mouth and pharynx never are in direct communication with the bronchial glands, and but rarely with the supraclavicular glands. Connection with the pleural dome also was never demonstrated. In the author's experiments in which aspiration of the germs directly from the mouth to the lungs could be excluded, it was found that the infection of the lungs when secondary to that of the cervical glands always took place through the blood stream, and therefore through the lymphatic duct and the vena cava. Observations on the bodies of infants showed that the chief and most long-standing lesion was always to be found in the bronchial glands, and he therefore concludes that in most cases the bronchial glands are the primary site of the tuberculosis invasion, while the cervical glands are a secondary affection that only in rare cases has anything to do with the origin of pulmonary tuberculosis in man. He believes that healthy unaltered lymph nodes form a filter that is impervious to bacteria and that the portal of entry in children's pulmonary tuberculosis is the lung itself or the bronchial tree, the germs gaining access to this either through the air or from the mouth, in which they accumulate through the presence of infected foods.

**Experimental Observations in Phototherapy.**—Schulz says that in the Finsen treatment two possibilities must be considered, the bactericidal action of light, and some specific effect of the light rays on the tissues. He reviews the more important observations that have been published in attempting to determine which of these factors is the essential one, and comes to the conclusion that it is still impossible to decide the question. He also describes numerous experiments he made in order to discover the effect of injecting sensitizing solutions such as erythrosin into the tissues before applying the light rays. An inflammatory reaction is always produced which by some authors has been ascribed to a deeper penetration of the light rays under these conditions. The author found, however, on making careful control observations that the effect produced was simply the result of the irritating properties of the erythrosin solution itself, and that, for example, the portion of a completely injected rabbit's ear that was subjected to the rays did not differ in the nature or extent of the reaction from the other injected but unilluminated portions of the ear. Although his experiments have given rather negative results so far, he does not believe that the matter has been conclusively settled, and he recommends a continuation of observations in this direction.

*Münchener medizinische Wochenscrift, August* 1, 1905.

**The Occurrence of Typhoid Bacilli in the Bile of Typhoid Patients, and "Typhoid Bacilli Carriers".**—Forster and Kayser term "typhoid bacilli carriers" certain healthy individuals who carry in their bodies and evacuate in their excretions typhoid bacilli, without themselves suffering on this account. Such persons, it appears, are by no means rare, and they are either people who have come in contact with typhoid patients without being taken sick, or who after recovering from the disease continue for months or years to throw off bacilli in the feces. The authors first undertook to determine the region of the body in which these bacilli proliferate and the manner of their excretion. Observations of various sorts lead them to conclude that it is particularly the gall bladder that serves as a lurking place for these bacilli, and they assume that in the course of events the germs on entering the body reach the liver and then pass into the bile stream and the gall bladder. From this breeding place they are washed down into the intestine, and so appear in the feces. A large proportion of the bacilli carriers agglutinate their organisms, but this is not a reliable means of detecting such individuals, for as the propagation of the germs is a purely local affair the serum is not always bactericidal. Thus two possibilities are suggested—either that a general infection does not take place in these persons, owing to a local immunity of the intestine, or that the usual portals of entry for the bacillus are to be found in a portion of the alimentary tract anterior to the duodenum. The task of rendering these bacilli carriers innocuous to their environment is a difficult one, and the most promising plan seems to lie in operation and local treatment of the gall bladder if there is any reason to suspect disease of this organ.

**The Demonstration of the Spirochæta Pallida in the Blood of Syphilitics.**—Noeggerath and Stachelin describe a procedure by means of which they have been enabled to demonstrate Spirochæta pallida in the blood of three patients with untreated secondary syphilis. At least 1 c.c. of blood was obtained from the lobe of the ear or from a vein by letting it drip into ten times the amount of .3 per cent. acetic acid. The solution was then centrifuged and smears made from different layers of the sediment. These were then stained with Giemsa's solution. The organisms were found without much trouble in each case, but not in the blood of six patients suffering from various non-luetic infections that were examined as a control. The authors attach much importance to this discovery of the spirochetæ in the blood of patients with acquired syphilis, and they believe that this is the first observation of this sort.

**The Passage of Ankylostoma Larvæ Through the Human Skin, and Its Significance.**—Bruns and Müller say that they had been inclined to agree with those observers who believed that it was impossible for infection of the intestine with ankylostoma larvæ to take place through the skin, but that on repeating the experiments of Loos, who takes the opposite view, they obtained confirmatory evidence of his assertions. Ten dogs were infected with the nearly related ankylostoma caninum by the application of larvæ to the back under precautions which precluded the possibility of mouth infection, and experiments on four human beings were followed by the appearance of eggs in the stools after the lapse of forty to fifty days. In both of these successful cases the inoculation was made through the foot, after the skin had first been softened by a prolonged foot bath. The demonstration of the possibility of this mode of infection naturally greatly increases the difficulties of prophylaxis in mining communities, but there is no reason to relax any of the precautions introduced to prevent oral infection, and it is essential to insist on still greater care than before in the disposal of feces.

*Deutsche medizinische Wochenschrift, August* 3, 1905.

**Paget's Disease of the Nipple.**—Ribbert uses the description of a case of Paget's disease and of one of a breast cancer with eczematous degeneration of the skin, to illustrate his views on the nature of carcinoma. He does not believe that Paget's disease is a primary carcinoma of the skin, and he denies that the cancerous cells found in the epidermis are metamorphosed epithelial cells which may be regarded as the basis of a malignant proliferation. These cells are the result of the development of a deeper growth, flourishing deeper down, independently of the skin, and the mass increases in size only through multiplication of its own cells. In this case, however, the growth is not confined within connective tissue septa, but progresses by an unusually extensive intraepidermal migration of the cells. This view of the nature of Paget's disease is another argument against the theory that the essential feature in carcinoma is a degeneration of epithelial cells. The question of carcinoma is not concerned with new sorts of cells, or with primary metamorphoses through which cells become endowed with the power of becoming structural units of tumor formation. The proliferative power is already present, only requiring to be set free, and it is the knowledge of the conditions that can accomplish this that is still wanting for a complete understanding of the nature of cancer.

**The Diagnosis of Influenza.**—Köppen says that the recognition of influenza during epidemics and endemics is usually not difficult, especially as until the epidemic begins to subside the cases commonly exhibit a great deal of similarity. Sporadic cases, however, present much greater difficulties of recognition, and the following symptoms aid in the differential diagnosis: A brief period of initial fever, the occasional occurrence of influenza bacilli in the sputum, which at first is viscid and contains few leucocytes, but later becomes more purulent; albuminuria, which at first is marked and later subsides, and diazoturia corresponding in duration to that of the illness itself. He attaches much importance to the simultaneous occurrence of the albuminuria and the diazo reaction, and says that this observation serves to distinguish infuenza from most other infectious diseases. Typhoid and tuberculosis, however, may give the same signs, and this triad must always be kept in mind when albuminuria and the diazo reaction are observed together in the early stages of an illness.

*The American Journal of the Medical Sciences, July,* 1905.

**Chondrodystrophy Fœtalis (Achondroplasia).**—D. J. M. Miller declares that the essential process of this affection is a defective one; in other words, it is a failure in growth of the peripheral proliferating cartilage cells. It is said that the disease begins in the earlier months of fetal life and runs its course before the third or sixth month. Those bones only which are formed in cartilage during early fetal life are affected. The bones laid in membrane, and those in which, although laid in cartilage, ossification does not begin until late in uterine life or until after birth are not involved, or, at the most, but slightly. Thus in a patient affected with this disease there would be normal growth of the clavicle, the sternum, the cranial vault, the vertebræ, the patellæ, the carpus, and the tarsus. The long bones of the extremities, however, the ribs, the pelvis, and the posterior part of the cranial base are stunted in growth. In the majority of cases the peculiar shape of the head is due to premature synostosis of the os tribasilare. The most important change in the long bones is defective or complete inhibition of the normal row formation of the cartilage cells along the line of ossification. These patients are generally fat, and they often show other congenital deformities. The majority of them are stillborn or die soon after birth. Practically nothing is known of the etiology of the disease. The parents are usually normal. When the patient stands, his height is far below that of the normal individual of the same age. The writer cites the history of a case which has come under his observation. The patient is a boy of seven years. He appears even brighter than most children of his own age. This mental condition is an apparent characteristic of these patients. The writer gives an interesting series of measurements of his patient, comparing them with the measurements of a normal child of the same age.

**Acute Peritoneal Infection and Its Relation to Intestinal Obstruction.**—James P. Warbasse states that, clinically, paralysis of the bowel is the same thing as intestinal obstruction, giving rise to the same symptoms. Upon opening the abdomen in the ordinary case of peritonitis with paralysis of the bowel, the surgeon sees many coils of distended and inflamed intestine. A small part of this disturbance is due to peritonitis. Intestinal obstruction develops, which in its turn gives rise to a dilatation of the bowel above, with paralysis and transmigration of intestinal bacteria from the mucous membrane to the peritoneum. In this event the peritoneum becomes inflamed. The surgeon generally sees it in the early stage when it is dry. Later on there is secretion, and it is then difficult to tell whether the paralysis of the bowel preceded or followed the peritonitis. In all cases of this kind there are present an infective paralysis below and a paralytic infection above. Although in text-books a great differentiation is attempted, the writer declares that the subjective symptoms of these two conditions are about the same, and are due to the same conditions.

**A Study of the Mesenteric Glands in Their Relations to Tuberculosis.**—Randle C. Rosenberger presents the following conclusions, after having studied the mesenteric glands in seventy cases: In all cases of active tuberculosis, and in almost all cases of inactive tuberculosis, the mesenteric glands are tuberculously infective. The mesenteric glands in these cases may or may not show gross evidence of tuberculosis or tubercle bacilli in spreads; the result is the same as far as the qualitative production of tuberculosis is concerned. The mesenteric glands, in a certain percentage of cases showing no tuberculous lesions in any part of the body, are tuberculously infective. In the present study the percentage was about forty. The tuberculous infectivity of the mesenteric glands is probably shared by the other groups of lymphnodes throughout the body.

**The Surgical Complications of Typhoid Fever.**—George G. Ross names as surgical accidents, perforation of the bowel, primary perforation of the gall-bladder, perforation of the appendix, peritonitis without perforation, acute intussusception, rupture of the peritoneal coat of the mesenteric glands, bone infections, phlebitis, parotiditis, and so on. Perforation of the bowel stands first in order of frequency. Probably perforation of the appendix during typhoid fever is next in frequency. There have been recorded thirty-four cases of primary perforation of the gall-bladder which occurred during the course of, or during convalescence from, typhoid fever. The history of the case is of great importance in making the diagnosis. Careful attention must be paid to the location of the pain and tenderness, and the existence of tenderness during the course of the fever over the gallbladder. It must not be forgotten that pain in the gallbladder region may be caused by rupture of perforating ulcer of the stomach near the duodenum or of the duodenum, or to acute diseases of the pancreas. During the course of an attack of typhoid fever the vermiform appendix is often involved. It is only in recent times that the question of treatment of the various disastrous occurrences mentioned in this paper has received the attention that it deserves. Although the large majority of such patients die, yet the writer believes that many could be saved if the condition were recognized early and operation were promptly performed. He states that the only reliable symptoms to be recognized in time to prevent disaster are pain and muscular rigidity.

**Protozoa in the Stomach and Their Diagnostic Significance.**—John Benjamin Nichols describes an interesting case in which protozoa were found in the stomach. Very few of these cases are reported in the literature. An examination of the necrotic fragments obtained from the stomach showed large numbers of actively moving flagellate protozoa, apparently trichomonads. In all of the cases reported flagellates were found, with associated amœbæ in a few instances. The chief organisms were trichomonas intestinalis and lamblia intestinalis (megastoma entericum). In the majority of cases only a single species occurred. In three cases the trichomonas was found also in carious teeth. In many of them the various protozoa were found also in the feces. The trichomonas and other flagellates that live in the alimentary passages seem to prefer there an alkaline or neutral medium. Another important condition for the presence of the parasites in the stomach is the existence of small recesses, pockets, or diverticula in the stomach wall.

The writer declares that the diagnostic significance of the presence of protozoa in the stomach cannot be formed until further observations are properly made with both negative and positive findings, not only in cancerous but also in non-cancerous conditions, and especially in noncarcinomatous cases of achylia gastrica. He thinks that the parasites will be found far more often if they are properly and systematically looked for.

**Surgical Diagnosis in General Practice.**—John B. Roberts calls attention to the importance to the general practitioner of a working knowledge of surgical diagnosis. Many diseases which could be easily managed by prompt treatment may, through delay, cause effects too far-reaching to be remedied. This is especially true in pathological conditions of a surgical character. The writer also points out the value of consultation properly conducted. Systematic study of cases cannot be too much emphasized. Objective symptoms are more reliable than subjective ones. After a definite diagnosis has been reached in surgery, the physician must not forget to look also for complicating or consecutive conditions. Another important point is the diagnosis of the constitutional resistance of patients. The extensive distribution of syphilis and tuberculosis should always occur to the physician when patients apply for diagnosis and treatment. The lesions of these two diseases are markedly similar. Finally, the writer emphasizes the value of the cooperative method by which each physician may profit by the special knowledge and trained senses of all of his professional colleagues.

*French and Italian Journals.*

**Presence of Spirochetes in the Lesions of Syphilities.**—Galli-Valerio and A. Lassueur draw attention to the presence of spirochetes in the lesions of syphilis, not only on the surface of chancres and mucous patches, but also in the depths of affected lymphatic glands. There are two species of spirochetes: one is large and is easily colored with analine stains, and has rather undulations than true spiral shape; it is Spirochæte refringens; the other very thin, difficult to stain, 4 to 14 ft. in length, with ten to fourteen spiral irregularities, is Spirochæte pallida. S. refringens has nothing to do with the production of syphilis, while Spirochæte pallida is in all probability the specific cause of syphilis. It has been found in the syphilitic lesions of man and the ape, never in lesions of any other nature. It has been found in the bullæ of syphilitic pemphigus, which had not been opened, in a child who had died of hereditary syphilis at ten months of age; also in the spleen, lungs, and liver. It has been found also in the blood of syphilitics, and in the liver on the day of a roseolous eruption. It has also been found in four cases of syphilitic glandular swellings, and in the primary sore and mucous patches, by several observers. The authors examined ten syphilitic cases, and give the following results: 1. In the condylomata of one syphilitic, and the mucous patches of five syphilitics they found spirochetes 4 to 10 μ long, presenting the characteristics of pallida, in considerable quantity. The germ colored in 9 to 12 hours with Michaelis' azure. 2. In one case they found no spirochetes in mucous patches, nor in the chancre or glands examined.—*Revue Médicale de la Suisse Romande*, July 20, 1905.

**Ankylostomata in Miners.**—Paul Fabre reviews the latest works on the presence of ankylostoma duodenale among miners. France has had very few cases among miners, while they have been frequent in the countries further north. Among the 0,000 miners of the Pas-de-Calais trichocephalus was found in 50 per cent. of the cases examined, but ankylostoma was found in only two cases, in the dejections of two men employed in the same mine. This represents 0.4 per 1,000 in these mines. The temperature of these mines is rarely high enough to propagate the parasite, while on the surface of the ground, at a higher temperature, they grow quickly. Also the workmen are very careful not to defecate in the mines. When obliged they use the wagons, so that the material is removed from the mine. Hence the mine does not become infected by them. The disease was not communicated to the families of these two patients, both of whom were married and had children. The infection is always found in individuals who have worked in mines in other countries, and have brought them into France. A physical examination of the patient gives no results, only the microscopic examination of the feces gives the parasites. There seems to be little bad effect on the physical condition of those affected that may not be ascribed to the other unhygienic conditions of their life. Ankylostoma seems not to be a grave malady in France, since those patients had not communicated the disease to their comrades during several months, having brought it from Belgium. It is predisposed to by heat, humidity, poor ventilation. In Saint-Etienne district the ankylostomosis is frequent, 92 out of 100 miners being affected, but of these only two were rendered unfit for work. In these mines they live much more indiscriminately, eating without washing their hands in the mines. Ankylostomiasis has a characteristic hematology; lessened red blood cells; less hemoglobin; hyponucleosis; eosinophilia; slight polynucleosis. The cerebrospinal fluid shows no changes. The author believes that the disease does not prevail sufficiently to warrant the stringent hygienic measures proposed to prevent its spread.—*Le Progrès Médical*, July 22, 1905.

**Treatment of Tuberculosis of the Testicle.**—P. Paul Réclus discusses the operative treatment of tuberculosis of the male genital organs. The diagnosis is easily made, except when the masses of tubercular tissue are very small, for they form nodules that are easily appreciated by touch, and that are exceedingly hard, while inflammatory nodules or their sequelæ in the form of fibrous tissue, are much softer and more elastic. The first structure to be attacked is the epididymis. The nodules are usually multiple, and surround the testicle. They are often caseous, or suppurate and leave fistulæ. If the case is one in which the lesion is old, and has become fibrous, the masses are harder, not sensitive to pressure and smaller than in the active stage. The treatment should be first medical; rigorous hygiene, fresh air, over-feeding, change of air, with arsenic internally and cod-liver oil in large doses. If the process goes on to suppuration operation becomes necessary. When the epididymis alone is affected an epididymectomy may be done under local anesthesia. If the nodules are large and many it is useless to temporize, and a castration must be done. A new operation has been proposed, the anastomosis of the deferent canal with the spermatic tubes. If the whole testicle is involved castration is done only under local anesthesia, single if possible, double if both glands are involved. In the latter case the patient is better satisfied if we can leave a portion of the testicle, so that he may be able to feel himself capable of erection.—*Journal des Praticiens*, July 22, 1905.

**Syphilis of the Pylorus.**—Cimoroni reports six cases of syphilitic ulcer of the pylorus, which had produced stenosis. The symptoms pain, hyperchlorhydria, and vomiting of food in such cases, which would ordinarily indicate a peptic ulcer, in a syphilitic subject should lead the physician to look out for a syphilitic lesion of the pylorus. The ulcer may affect the entire mucous membrane, while the muscular tunic is invaded by sclerogummatous tissue, which has an effect quite opposite to cicatrization, or may produce stenosis of the organ. There may coexist with this multiple intestinal stenoses of syphilitic origin. From a diagnostic point of view it is well to note that the symptoms of peptic ulcer, manifesting themselves in an old case of syphilis, should lead us to suspect pyloric stenosis. In such cases antispecific treatment may bring about a cure and at the same time elucidate the diagnosis.—*La Riforma Medica*, July 22, 1905.

**New Method of Preserving Milk.**—L. Spolverini and M. Flamini bring forward a new method of preserving milk, by means of an atmosphere of carbonic-acid gas, under pressure. The milk remains unaltered for several days, both in its physical and chemical characters, and in the biological constituents, the ferments. Some of the germs present are killed, while others have their development arrested. Only one kind remains unchanged, a diplostreptococcus, not pathogenic, which after some days, with a suitable temperature, coagulates the milk. Uncooked milk can be kept for 8 to 12 days at a temperature of 12° to 14° C., while boiled milk is preserved indefinitely. The production of the gas is without difficulty practically. This method of preservation assists us in solving the question of the feeding of children with milk sterilized by heat, in preference to cooked milk, since it permits us to keep the milk for a considerable period deprived of all pathogenic germ action, and to preserve all its biochemical functions, which are lost by heat sterilization.—*Rivista di Clinica Pediatrica*, July, 1905.

**Congenital Laryngeal Stridor.**—O. Cozzolino tells us that there is a form of laryngeal spasm that is of congenital nature, and which is a true morbid entity, the basis of which is a true malformation of the larynx, epiglottis, ari-epiglottic folds, and rima glottidis. Another very similar form must be distinguished from this, which is not congenital: it may be distinguished by the tone of the respiration, and by being secondary to other diseases of the throat, such as adenoids, hypertrophies of nasal structures, and bronchial affections. The characteristics of the secondary form of spasm are its coming on by attacks, and its rapid disappearance when the primary conditions are removed. This form is accompanied by inspiratory sinking in of the thoracic walls, and less marked cyanosis. In the congenital variety there is a nervous element present, as well as the anatomical one. The prognosis is favorable. Death rarely occurs, but may be due to an added pneumonia, or bronchopulmonitis, to which the bad formation of the larynx predisposes the child.—*Rivista di Clinica Pediatrica*, July, 1905.

# Book Reviews.

Select Methods in Food Analysis. By Henry Leffmann, A.M., M.D., Ph.D., and William Beam, A.M., M.D., F.I.C. Second Edition, Revised and Enlarged. With One Plate and Fifty-four Other Illustrations. Philadelphia: P. Blakiston's Son & Co., 1905.

The subject of food adulteration and its detection has become so prominent of late that the demand for laboratory manuals dealing with this branch of analytical chemistry has been much increased. The first edition of the present work was very favorably received, and in its present enlarged form it should prove still more acceptable. Some of the additions are: more detailed descriptions of apparatus; new processes for the detection of coloring matter and preservatives; analytic data in regard to fruit juices, jams, and jellies; rapid methods for the examination of flavoring extracts, condensed milk, and cereal foods, etc. It has been the object of the authors to keep the volume as concise as possible, but while within limits this is a virtue, we think that they have erred somewhat in the direction of brevity. The general discussions of the nature of adulterations likely to be encountered in the different foodstuffs might with advantage be amplified, and although the microscope is illustrated and its use is briefly described, the references throughout the text to the application of microscopical methods in the detection of adulterants are very incomplete. This method of investigation is worthy of much greater space in the letterpress, and especially of a great increase in the number of illustrations. The important subject of the detection of parasites in infected meats, for example, has no illustrations whatever, and is dismissed with less than twenty-five lines of text. Such brief mention is useless for the instruction of the tyro, and contains nothing of interest to the more experienced worker. Another notable omission is the absence of any reference to the precipitin method for identifying the substitution of inferior sorts of meat, *e.g.* horse flesh, for more expensive varieties, or for determining the varieties present in sausage or chopped meats.

A Manual of Practical Hygiene for Students, Physicians, and Medical Officers. By Charles Harrington, M.D., Assistant Professor of Hygiene in the Medical School of Harvard University. Third Edition, Revised and Enlarged. Illustrated with Twelve Plates in Colors and Monochrome, and One Hundred and Eighteen Engravings. Philadelphia and New York: Lea Brothers & Co., 1905.

The appearance of this book in the third edition is sufficient testimony to the rank it has taken among the ever-increasing volumes on hygiene. The text is presented in nineteen chapters. The subject of food in its various aspects is first treated, considerable space being devoted to it. After general considerations, the various special foods are discussed from different standpoints. The inspection of food, its composition, analysis, preservation, and adulteration are all considered. One section is devoted to the description of beverages. Condiments, spices, and bakers' chemicals are treated in another section. The section on contamination of foods by various metals, such as copper, lead, zinc, nickel, tin, and contamination by kitchen utensils, is both practical and interesting. Still other subjects discussed are air, the soil, water, habitations, schools, ventilation, heating, lighting, plumbing, disposal of sewage, disposal of garbage, disinfection, military, naval, marine, and tropical hygiene, hygiene of occupation, vital statistics, and personal hygiene. The subjects are treated with a breadth of view which is admirable. Nevertheless, careful attention is paid to details, the result being a complete, clear, well-illustrated volume which will prove of great value to the student, practitioner, health officer, and general reader. The author has carefully revised the work, cutting out all obsolete material, while he has added much that is new. The new section on Infection, Susceptibility, and Immunity is most interesting, and of great value.

The Complete Kano Jiu-Jitsu (Judo). The Official Jiu-Jitsu of the Japanese Government, with the Additions by Hoshino and Tsutsumi, and Chapters on the Serious and Fatal Blows and on Kuatsu, the Japanese Science of the Restoration of Life. By H. Irving Hancock, Author of "Japanese Physical Training," "The Physical Culture Life," "Life at West Point," etc., and Katsukuma Higashi, One-time Instructor in Kano Jiu-Jitsu at Doahisha College, Kioto, Japan, and now Professor of Jiudo in New York City. Illustrated by over Five Hundred Plates from Life, and Four Charts. New York and London: G. P. Putnam's Sons, The Knickerbocker Press, 1905.

The authors state that this is the first complete and authentic work in any language that explains the highest school of jiu-jitsu, as that art is taught and practised by the adepts of Japan. It appears that the system at present recognized by the Japanese Government is an improvement on the older methods, introduced within comparatively recent times by Professor Jiguro Kano, and amplified by two of his colleagues, Hoshino and Tsutsumi. Jiudo is technically the correct term to apply to what the Japanese people generally still call by the popular name of jiu-jitsu. The book is a truly beautiful production, and consists of over five hundred admirably executed photographs of two Japanese jiu-jitsuians at work, the various phases of each trick being set forth in the explanatory text. The one hundred and sixty tricks of the perfected system are divided into three sections. The first is devoted to the more or less preparatory tricks, the second to more advanced work, and the third to the highly scientific tricks of actual combat to be used for self-preservation in emergencies, and by which, when necessary, an adversary is maimed or killed. The book closes with several charts, on which are indicated the points at which blows causing death or unconsciousness may be struck, and finally, with an exposition of the science of Kuatsu, or the restoration of life. This, it is stated, was originally employed solely for reviving the victims of attacks, but it was later discovered that it was also potent in cases of drowning, sunstroke, and injuries from other accidental causes. The manipulations consist essentially of percussion, or massage of the great nerve centers, together with artificial respiration, and it is claimed that by their aid it is possible to bring back to life individuals who could in no other way be resuscitated. The book should have an interest for medical men, even if they never expect to practise the system it teaches.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; assisted by H. R. M. Landis, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. June 1, 1905. Philadelphia and New York: Lea Brothers & Co.

The current number of Progressive Medicine consists of five parts, by different writers. The first deals with hernia, and is contributed by Dr. W. B. Coley; the second is on Surgery of the Abdomen, exclusive of hernia, and is by Dr. E. M. Foote; the third section deals with gynecology, and is furnished by Dr. J. G. Clark; the fourth, from the pen of Dr. A. Stengel, treats of Diseases of the Blood, Diathetic and Metabolic Diseases, Diseases of the Spleen, Thyroid Gland and Lymphatic System; and the last, on Ophthalmology, is contributed by Dr. E. Jackson. The literature of these various subjects has been carefully gleaned by competent hands, and the results are here presented in a readable form.

The Surgical Assistant; A Manual for Students, Practitioners, Hospital Internes, and Nurses. By Walter M. Brickner, B.S., M.D., Assistant Surgeon, Mt. Sinai Hospital, Out-Patient Department, etc. With 123 Original Illustrations. New York: The International Journal of Surgery Co., 1905.

The preparation of this book should win for the author the gratitude of the entire tribe of aspiring young surgeons whose anxiety to shine in their subordinate posts is often hampered by ignorance of exactly what is expected of them. The duties of the assistants during grave operations are extremely responsible, and complicated procedures cannot be carried out with the necessary *aplomb* unless the several participants are well schooled in their parts. The author has undertaken to supply precisely this information, which heretofore has been obtainable only through actual experience. The first part of the volume is devoted to the general principles of assistantship, and comprises two chapters of common sense advice on the personal conduct of the younger men to their superiors and to patients, followed by others on assistance in examinations and dressings, the preparation of an operating room in a private house, the technique of asepsis, the anesthetist, the care and handling of instruments, assistance at the wound, and the post-operative care of the patient. In the second part the assistant's duties are discussed from the standpoint of regional surgery, and the chief operations on each part of the body are described in turn, with the necessary directions for the assistant. One appendix is devoted to the preliminary treatment and the routine after-treatment of operative cases, and a formulary; another consists of 116 illustrations of the instruments most often used. These are in addition to the numerous and very practical illustrations in the body of the book. While the ability to anticipate and carry out each wish of the operator almost before he has had time to formulate it in his own mind can be acquired only by much practice, study of the many hints given in this volume should greatly shorten the period of apprenticeship, and we imagine that both operators and their would-be aides will view its appearance with interest and pleasure.

### SECTION OF SURGERY.

*Second Day—Thursday, July 27.*

**Treatment of Malignant Disease of the Rectum.**—Sir CHARLES BALL, in opening this discussion, said that the most recent work on this subject had been rendered more mature and perfect by the halt which had lately occurred, and that they might gain even greater advantage from it if they were to mark time, as it were, whilst they reviewed their position. He had, therefore, decided to give a résumé of the treatment of this condition. He hoped that the cancer research work to which so much attention was now being paid might result in the discovery of a cure for this terrible malady, and that the hypodermic needle might then prove, by some form of serum treatment, more efficacious than the knife; but in the meantime he was quite sure that attention to the details of technique and an early diagnosis were of vital importance. In this latter direction a great responsibility rested upon practitioners to examine their patients whenever there was the least suspicion as to the nature of the condition in any rectal trouble. In attempting to decide whether the case was one for operation or not, the principal points were whether there was a secondary gland invasion (though he did not consider that glands in the hollow of the sacrum contraindicated operation; for they could be removed at the same time as the rectum) and whether fixation of the growth had occurred. If the growth were deeply fixed, showing invasion of surrounding structures beyond the rectal wall, operation was useless. In all these cases of rectal cancer the mucous membrane was early involved, and was not movable over the growth; if it was, then the case was not one of cancer, though it might be of sarcoma. Before operation proper preparation of the patient was most important, and the bowels must be thoroughly unloaded by aperients and enemata over some days. The speaker then showed a series of lantern slides to illustrate the various anatomical points in connection with the rectum, which were involved in the modern operation for excision. In the first, he showed that the anal canal was almost at right angles to the main axis of the rectum, and he said that it was of supreme importance to keep the sphincters and pelvic sling or diaphragm intact, so that incontinence might not follow the operation. He considered that the perineal incision was out of date, and should be discarded, since it divided this pelvic sling, and incontinence of feces always followed. He then showed a slide in which the rectum was markedly bulged forward just above the anal canal, forming an anterior pouch behind the base of the bladder, and this he regarded as one of the favorite seats of cancer of the rectum. The next slide displayed the pelvic colon with its mesentery, the colon being lifted up so that the full extent of the mesentery might be seen. He regarded the length of the mesentery line as of great importance, for a little dissecting up allowed the lower end of the pelvic colon to be brought down to the anus after the removal of the rectum. The mucous membrane of the anal canal should then be dissected off, and the lower end of the bowel passed out through the anus, and stitched to the skin; in this way perfect control over the feces and even over gas was retained. He regarded this plan as of greater value than end-to-end union of the upper segment with the lower, after the excision. When end-to-end union was tried, it almost invariably failed; for even if union took place, it was broken down again by the passage of the first water, which usually contained a few scybala. The perineal operation was advisable only for cancers lower down, involving only a comparatively small part of the circumference of the rectum, or for cancer of the anal canal. In cancer higher up the rectum, a Kraske operation gave more room. The operation had been much modified, and Bodenhamer's was the one that he regarded as the best. The anus was left intact, and an incision made from the middle of the sacrum downwards over the coccyx which was then cleaned, a transverse incision through the fifth sacral vertebra was than made and the coccyx and fifth sacral vertebra removed by cutting with American pruning shears. If necessary, more room still could be obtained by cutting away more bone. A dissection down onto the posterior rectal wall was now made, and the peritoneum opened deliberately each side; a ligature was passed round the superior hemorrhoidal artery, and one on each side round the two middle hemorrhoidals, which lay in the lateral false ligaments of the rectum. A loop of bowel was now hooked out and a gauze sponge placed in front of the bowel to protect the peritoneal cavity. The bowel was now ligatured and divided above the growth, which was then freed with the finger and the knife, and ligatured below the growth. The upper end was now brought down through the denuded anus, and stitched to the skin. A sacral anus was very rarely necessary, as the upper segment could usually be brought down if freed by a slight dissection. He considered, however, that there was a great future before the abdominal operation, when combined with the previously described method of dealing with the lower end of the upper segment. It enabled a thorough examination and an estimation of the extent of the disease to be made; also it was possible to ascertain whether there was serious involvement of the lymphatics, or deposit in other viscera, such as the liver. It could, if necessary, be terminated by a simple colotomy if the disease was found to be too extensive for removal. The pelvic colon was divided above the growth and at the point where its mesentery was longest, if not more than four inches, the operation was finished as a colotomy; otherwise, after the dissecting out of the lower piece of bowel down to the anal canal, this portion of bowel was divided below the growth and removed. The upper segment was then brought out through the anus and stitched to the skin. He considered that the operation would be more used in the future than it had been hitherto.

Prof. HARTMANN of Paris said that in the performance of Kraske's operation, he laid great stress upon technique. He used methods practically identical with those of Sir Charles Ball. He reported twenty cases of excision of the rectum with only one death. He regarded the abdominal operation as a very valuable one.

Mr. EDWARDS considered that the diagnosis of cancer high in the rectum was attended with considerable difficulty, and he regarded Strauss's electrical speculum as a very great assistance in these cases. He thought that an anesthetic should be given in all these cases, especially with a view to ascertaining whether there was mobility of the rectum or not, and he said the patient should in all cases be placed in a modified Trendelenburg position in order that the superincumbent weight of the viscera might be removed, as it was an impediment to the estimation of fixation of the rectum. He had operated in forty cases, and one patient was now living, ten years after the operation. He advised a previous colotomy in cases where the peritoneum might be involved, as it enabled this point to be further investigated and more easily dealt with at any subsequent operation.

Mr. F. C. WALLIS showed a series of lantern slides illustrating the anatomy of the region and some of the points in operative treatment. In the perineal section he made an inner and outer ring incision, and removed the anal canal and lower part of the rectum. When the cancer was higher and upon the anterior rectal wall, the operation through the posterior wall of the vagina was useful. For cancer in the posterior wall, and high up, he advocated Kraske's operation, and divided the sacrum transversely at the third sacral vertebra; though by a diamond-shaped incision in the bone, the apex of which reached the third sacral vertebra

in the mid line, a great deal of bone was saved and sufficient room, as a rule, obtained. He considered that fixation of the rectum could only be properly ascertained under an anesthetic, and when it was present no operation should be undertaken. In Kraske's operation the resulting wound should be left widely open and lightly packed with iodoform gauze, very free drainage being essential.

Mr. Sinclair White said that he had performed excision of the rectum twenty-six times, but had not had very good results from it. He thought an abdominal section was the proper method to use to ascertain mobilization of the rectum, and to examine for dissemination in other viscera, the peritoneum, or the deep abdominal glands. He advocated a preliminary colotomy in Kraske's operation, for it did not add to the patient's danger, and could be subsequently closed if desirable, whilst it diverted the feces during the healing of the excision wounds. He said that cancer was very common at the junction of the anal canal with the rectum, just as it was all through the alimentary canal where two parts of the canal met, which differed markedly either in their function or development. He showed a specimen of a diverticulum arising from the rectum in this region, which he thought probably owed its origin to partial persistence of the neurenteric canal.

Mr. A. B. Mitchell said that inversion of the rectum would prove an advance in the abdominal method, although he had not had an opportunity of trying it. He considered that in all these operations upon the rectum the grave danger was wound soiling from intestinal contents, and great care should be taken to avoid this.

Mr. T. G. Atkins regarded Strauss's speculum as of great advantage in the diagnosis of these cases, and he further advised deep anesthesia in the Trendelenburg position when doubt existed. He held that a radical operation should be performed whenever possible, and that moderate glandular affection was not a bar to it.

Mr. Stanmore Bishop regarded an early operation as the most important point in the success of the cases, and this involved the question of early diagnosis. In his opinion the point which first attracted the patient's attention was some alteration in the mode or manner of defecation. There might be no pain and no bleeding, but the patient would suffer in some cases from alternating constipation and diarrhea, or his motions might be difficult; but whatever form of change it might be, he laid stress upon the fact that some alteration from the normal took place in this function. He advocated preliminary colotomy, and considered that it advanced likelihood of a successful result from the operation by allowing complete emptying of the bowel before operation.

Mr. E. Deansley thought that some involvement of surrounding structures was not incompatible with excision of the rectum, but that any involvement of the bladder or ureters contraindicated it, and this matter should receive due attention before any operation was performed. It was the early cases which gave ideal results. When colotomy was performed, as it had to be in some inoperable cases, it added greatly to the comfort of the patient to wash out the rectum and lower part of the bowel every morning by an enema; further it gave great relief for as long even as six months to curette the rectum freely in some of these cases. He did not advocate a preliminary colotomy where excision was going to be performed. The lower end of the upper segment should always, if possible, be brought down to the anus after excision of the rectum. In operating by the perineal route, he advised placing the patient in the prone kneeling position with the legs and thighs over the end of the table; in fact, the position in which the dead body was placed for dissection of the buttock. In Kraske's operation the whole rectum should always be removed, the pelvic colon being brought down to the anus.

Mr. C. Ryall advocated an anesthetic for examination. He did not think the involvement of a few presacral glands precluded operation. He was against a preliminary colotomy in Kraske's operation. He had performed excision of the rectum, and the patient was out of bed in fourteen days; he thought one could not ask for anything better than that. He considered it of great importance not to cut or break into the growth, and scatter it broadcast through the wound. The peritoneum should be opened early in Kraske's operation, for the operator then knew where he was, and could more easily separate the anterior aspect of the rectum from the bladder.

Mr. Jackson Clarke said that he had seen a case where it was extremely difficult to diagnose between cancer of the rectum and ulcerative colitis; in fact, it was only the microscope which enabled a decision to be made. He advocated a preliminary abdominal section, and considered that the sacral route would become less common.

Sir Charles Ball, in closing the discussion, said he had listened to the various remarks with great pleasure and thanked Prof. Hartmann and the other speakers for the part they had taken in the discussion. He thought an anesthetic quite unnecessary in most cases for the purposes of examination, and it certainly added to the patient's troubles. He did not agree with those speakers who advocated a preliminary colotomy in all cases of Kraske's operation; he thought that it should be reserved for those cases where there was too severe a block to allow of the proper emptying of the rectum by aperients and enemata; in these cases he thought it was advisable, because without it the bowel could not be freed of the accumulated feces, and the patient had not been brought into a suitable state for operation. Further, he would use it in cases where the patient was very weak, and the conditions required immediate relief. As a general rule he considered that the colotomy should be a colotomy at the anus; that was to say, the rectum having been excised, the colon should be brought down to the anus, and should open there, not upon the outer abdominal wall. He was rather in favor of a preliminary abdominal section in doubtful cases; this had great obvious advantages, and he thought that the abdominal route would be more frequently used than it had been, for a preliminary abdominal section naturally led them to the abdominal operation. He had seen one case of cancer of the rectum—a case in which no possible clinical doubt could exist—get well spontaneously; and he considered Mr. Jackson Clarke's case of ulcerative colitis of interest as showing that diagnosis was sometimes scarcely possible. He was quite unable to account for the case he mentioned; the patient got perfectly well and the lumen of the bowel was restored. The patient had not used anybody's serum, nor even violet leaves. He did not pretend to be able to give any explanation of the recovery. He thought the diverticulum of the rectum which Mr. Sinclair White had shown was more likely to have arisen in the post-anal gut than in the neurenteric canal, and he thought that many of the tumors and some malformations in this region occurred in connection with the post-anal gut. He had seen a specimen of a tube which probably had arisen in connection with the neurenteric canal; it occurred in connection with a spina bifida and ran from it to the rectum, into which it opened; it was shown to him by Mr. Wheeler.

**A Modified Finney's Operation.**—Mr. Sinclair White showed some diagrams and read a short paper upon a modification of Finney's operation of gastropyloroduodenostomy. He performed the same operation but stitched up his aperture by the ordinary gastrojejunostomy method instead of by the mattress suture which Finney employed.

**An Unusual Condition of the Large Intestine Associated with Carcinoma in Three Sisters.**—Mr. C. P. Childe reported these cases. In the first sister a hard mass of cancer was discovered in the rectum and several soft masses were felt above which were apparently villous in character. The rectum was excised and the patient died on the fifth day. No post mortem was allowed, but the question arose as to whether the villous growths felt higher up were becoming malignant.

The second sister had cancer of the rectum at the same time, and the third sister was found some three months

later to have cancer of the rectum also. They declined operation. Similar cases of cancer of the rectum in families had been reported by Allingham and Harrison Cripps.

Sir Charles Ball said that he regarded these multiple polypoid growths of the mucous membrane as comparable to warts upon the skin. They resembled them in that under certain conditions they might become malignant, just as a wart might, and in that they sometimes occurred in families. He recalled the fact that it was not uncommon to see the multiple warts of children present in several members of the family. The question of possible infectivity must not be lost sight of.

**A Blood Cyst of the Omentum.**—Mr. L. A. Bidwell reported this case. There was a large quantity of ascites, which were thought to be of malignant origin. An operation was performed with a view to letting out the fluid and exploring the abdomen. Four gallons of fluid were let out and a tumor was found attached to the omentum. It was ligatured off and removed. It contained blood, and appeared to be a sarcoma, but a microscopical section of the wall rendered this doubtful. The patient made a good recovery.

**Epigastric Invasion of the Abdomen in Breast Cancer.**—Mr. Handley Sampson read a paper on this subject. He accompanied his remarks by a lantern demonstration showing the lymphatics of the breast and pectoral region. He considered that some of the lymphatics ran down to the epigastrium in the fascial layer beneath the breast, and that at the epigastrium the fascia came into very close connection with the peritoneum. He showed a slide of a microphotograph in which cancer cells were invading the peritoneum in this region, and he believed some found their way into the liver by the falciform ligament, and others were showered into the peritoneal cavity, thus accounting for secondary deposits in the liver and portal glands and peritoneum. These secondary deposits were quite unaccounted for by the embolic theory, owing to the undue percentage of occurrence in these regions secondary to cancer of the breast. He, therefore, advocated the removal of the fascia of the epigastrium in addition to the ordinary removal of the pectoral fascia, and held that it added but little to the length or gravity of the operation.

SECTION OF OBSTETRICS AND GYNECOLOGY.

*Third Day—Friday, July 28.*

**Treatment of Albuminuria and Eclampsia.**—Dr. Robert Boxall opened this discussion. He said that though the actual cause of eclamptic fits was unknown, it was now generally agreed that they were due to faulty metabolism of kidneys and liver. Eclampsia was more common in primiparæ, and this was supposed to be due to increased intraabdominal pressure; the liability to the fits increased as the pregnancy advanced, and was worse in the case of twin pregnancy and hydramnios. At the end of pregnancy albuminuria subsided, and generally disappeared. Eclampsia was almost invariably associated with albuminuria. Eclamptic seizures were more common in the albuminuria of pregnancy than in other albuminurias, and the severity of the fits bore a rough relation to the amount of albumin and amount of urea excreted. Post-mortem there were found parenchymatous changes in liver and kidneys.

The statistics of the Registrar General showed that the proportion of deaths from puerperal convulsions was less in London than in the rest of the Kingdom.

Prophylactic treatment consisted in testing the urine in every case of pregnancy during the last three months; and in all cases where albumin was found the patient should be at once put on a suitable diet, which should be mainly milk; no meat should be allowed. Tarnier's system was to give water only for forty-eight hours, and afterwards skimmed milk. Purging should be procured by salines and copious enemata of saline solution. The skin should be encouraged to act. If there was no improvement under this treatment the pregnancy must be terminated. If fits supervened on the albuminuria they must be got under as soon as possible by chloral and bromide by mouth or rectum, hot pack to body, and ice cap to head, the patient being afterwards enveloped in blankets, with poultices to the loins. When the fits rapidly succeeded one another the attendant should give chloroform; when at longer intervals, morphine. Venesection and intravenous infusion of saline solution were also advised.

The question of emptying the uterus then arose, and this should be done with a minimum degree of interference, using chloroform for the later stages. For dilating the cervix one could use the Champetier de Ribes bag, the finger, Bossi's dilator, or incisions; he had not tried the two latter. Delivery might be completed by forceps, craniotomy, version, or finally cesarean section, abdominal or vaginal; the latter he condemned.

Professor Hastings Tweedy said that a common cause of death in eclampsia was edema of the lungs, and this was often due to fluid or medicines being put into the mouth while the patient was lying in an unconscious condition on the back. The following was the treatment in vogue at the Rotunda Hospital. Morphine was given, up to two grains in 24 hours; a soft tube was passed into the stomach and the latter was washed out with warm water, and then two ounces of castor oil with one or two minims of croton oil were passed in per tube, followed by one and one-half pints of fluid which was left in. The rectum was then washed out with copious quantities of water; the patient was kept on her side. Poultices were applied to the loins and saline solution was infused under the breasts. Nothing more was done. Labor was not induced or even hastened.

Prof. Byers of Belfast said that eclampsia was five times more frequent in primiparæ than in multiparæ. The fetus had a share in its production as was shown by improvement following on the death of the fetus and by its association with twins. As regards treatment he considered morphine preferable to chloroform, and he would expedite delivery under certain conditions.

Mrs. Scharlieb of London said that in India she had found lesions in the liver on post-mortem examination, and had seen some cases in which there were convulsions without preceding albuminuria. She used chloroform and allowed labor to proceed naturally.

Dr. John Campbell of Belfast used morphine and allowed spontaneous delivery, but some cases required manual dilatation and extraction.

Dr. Thomas Wilson of Birmingham had observed eighteen cases; seven of the patients died. He had noticed great dissimilarity in cases: some were preceded by blindness from retinitis, and others by dyspnea. He had given up the free administration of chloroform, and had seen much benefit from intravenous injections of saline solution. He advised performing vaginal cesarean section in some cases.

Dr. Holmes of Dublin said that in his experience some of the worst cases began after labor. He advised the use of morphine.

Dr. Inglis Parsons of London used pilocarpine.

Dr. MacLean of Cardiff had tried Bossi's dilator with disastrous results. He had found that thyroid extract increased the flow of urine.

Dr. Purslow of Birmingham said that in his opinion the greatest difficulty was to decide what to do in those cases in which fits came on badly at the end of pregnancy, but there was no commencement of labor. He had tried both the expectant and the active plan of dealing with the uterus in those cases, and on the whole had obtained the best results from the former.

Dr. Sharp of Nottingham dwelt on the importance of worry as a cause, and thought that statistics would show that the complaint was more common in the unmarried.

Dr. Corby of Cork said that pilocarpine caused excessive salivation and was dangerous on that account. He was

opposed to the use of morphine, but believed in saline infusion.

Dr. Ford Anderson of London said that his practice was to rupture the membranes; he thought chloroform dangerous, and advised amyl nitrite.

The President had felt it his duty to give a trial to Bossi's dilator, but had come to the conclusion that it was a "murderous weapon." Morphine was the best means of checking convulsions but might easily be pushed too far. He was not in favor of cesarean section. Pilocarpine was dangerous on account of its causing excessive secretion in the bronchial tubes.

Dr. Boxall, in closing the discussion, said that he did not wish to be considered an out-and-out advocate of accouchement forcé, and advocated it only when the patient was going on badly under other treatment.

**Elephantiasis of the Vulva.**—Dr. MacLean of Cardiff reported this case. The mass was removed from a girl aged 19, whose father had probably been the subject of syphilis and had lived abroad. There was a tumor of each labium minus, the size of a large orange, and elephantiasis of one leg was also present. He discussed the pathology of the condition at length.

**An Operation for Prolapse of the Uterus.**—Dr. Inglis Parsons of London read a paper with this title. The operation consisted in injecting a solution of quinine into the broad ligament so as to set up effusion. Full details of the method of procedure had been published in a previous paper. He reported 93 cases with good results in nearly all. Seven of the women had become pregnant subsequently, and had gone through a confinement with no bad effects.

A vote of thanks to the president was proposed by Prof. Byers of Belfast, seconded by Dr. Taylor Young of Sydney, Australia, and carried by acclamation. This concluded the business of the section.

---

SECTION OF TROPICAL DISEASES.

*First Day—Wednesday, July 26.*

**Address of the President.**—Dr. R. W. Boyce of Liverpool gave a brief summary of the year's progress in tropical medical science. Though the record was perhaps not so rich in discoveries as last year, it showed both a great increase in the amount of careful scientific observation, and the practical good of the application of scientific knowledge to the prevention of disease over an ever-widening area of the world. Thomas' exhaustive experiments had proved the value of the arsenic compounds in the treatment of the various trypanosoma diseases of animals. Very valuable work had been done in connection with the kala-azar parasite by Rogers, Leishman, Donovan, Christophers, and others. Tick fever had been elucidated by Ross, Milne, Dutton, and Todd. New protozoal parasites had been discovered in various animals by Bentley, James, Patton, Balfour, Christophers, and Castellain. Surely no other department of medical science could show such activity as this, nor did there exist one that deserved to be more strongly supported. It was indeed most interesting to note that as the result of all these investigations there had sprung up amongst the medical workers themselves a demand for the cooperation of allied sciences. A very large amount of the work in tropical medicine consisted in the study of the life history of parasites and of insect-hosts, and the medical investigator constantly found his progress hindered through want of the necessary knowledge in these subjects. The help must come from the zoological side, and it was coming, and the dipterologist, helminthologist, or protozoologist, was now usually to be found in any well-organized tropical medical laboratory. The study of the mosquito had engaged the attention of numerous dipterologists, and the habits of these insects were being worked out in all parts of the globe. The biting flies, injurious to man and animals, were coming in for a very large share of attention, and lastly, the study of ticks and fleas, so neglected in this country, had now, thanks to the medical investigators, been taken up in earnest by the zoological specialist. Tropical medicine and economic zoology were intimately bound together and they should prove the most powerful combine to attack those diseases which equally affected both man and animals, and which hindered progress in all tropical countries. A most interesting outcome of the tropical medical movement was the remarkable activity displayed by the Indian Medical Service, the Royal Army Medical Service, and the Colonial Medical Service, now that encouragement had been given to prosecute researches into tropical diseases. This increased scientific activity was also seen amongst the young doctors on the tropical coasting ships and amongst those in charge of mines and industrial concerns in the tropics. Prophylactic work in tropical countries had yielded splendid results as shown, for instance, by the remarkable decrease of yellow fever in many South American towns, as the result of organized campaigns against the stegomyia mosquito. Unfortunately, however, antimalarial measures were often more talked about than pushed on with, and the sanitation of some of the oldest coast towns within the tropics was a blot on British administration.

**Tick Fever.**—Major R. Ross of Liverpool opened the discussion on tick fever, reading a paper by Drs. G. Everett Dutton and John L. Todd of Liverpool, on "The Nature of Human Tick Fever in the Eastern Part of the Congo Free State with Notes on the Distribution and Bionomics of the Tick." On November 26, 1904, Dutton and Todd sent a message to the committee of the Liverpool school saying that they had discovered that a spirillum was the specific agent of human tick fever in the Congo, and that they had been able to infect monkeys through the bites of ticks. On March 24, 1905, they received the *British Medical Journal* for November 26, 1904, containing Ross and Milne's paper on tick fever, and recognized that the priority of the discovery belonged to these observers. In all parts of Africa where it occurred the tick (*Ornithodoros monbata*) was generally found to have an evil reputation amongst the natives. It was after leaving Stanleyville, on their way up the Congo to Kasongo, that Dutton and Todd encountered the tick and saw cases of the disease. At Nyangwé they were able to collect numerous ticks for experimental purposes and were able to perform an autopsy on the only fatal case of tick fever they met with. They reached Kasongo on November 23 and were attacked themselves by the disease. The period intervening between the bite of the tick and the declaration of the disease was about one week. The natives usually put it at five days. The onset of the disease was always sudden and in no instance preceded by a distinct rigor. The patient was prostrated and complained chiefly of severe headache. Boneache in the limbs and backache were distressing. There was a marked distaste for food. Vomiting generally occurred once or twice, but was never continued. Slight diarrhea was fairly constant. The evening temperature during the attacks frequently reached 104.5° F.; the highest temperature recorded was 105.3° F. There were usually three or four attacks which often ended in more or less profuse perspiration. As a rule, each attack lasted for three or four days and the intervening periods varied from five to nineteen days. The spleen was sometimes, though not always, enlarged. Herpes, epistaxis, and hiccough were complications observed. The most characteristic feature of the disease was the prostration of the patients during the attack of fever and the quick return to comparative health with the fall of temperature.

The mortality from tick fever was low amongst those who were cared for and not exposed to fatigue and hunger. Under adverse conditions it might be high; for example, of twenty carriers who contracted the disease in one caravan sent from Kasongo to Kabambarre ten died. Sir John Kirk said that after recovery from tick fever the patient enjoyed complete immunity from further attacks. It seemed very probable that those living in infected localities might have spirillum fever while young, and grow up immune to

the affection. When bitten, the natives burned the ticks they were able to capture, then they cut the skin at the site of the bite and rubbed in the ashes of the acarid as a preventive against the fever. Dr. Livingstone mentioned an analogous practice. In preparations colored by modifications of Romanowsky's stain the spirilla of tick fever stained unevenly and varied greatly in length. The largest spirilla measured 43 $\mu$, the smallest 13 $\mu$. Y-shaped, apparently division forms, and groupings of pairs, trios, and tetrads of spirilla were frequently seen in films taken from either patients or animals.

The spirillum did not kill the ordinary laboratory animals. To monkeys (species of *Cercopithecus*) it seemed uniformly pathogenic, especially to young ones. An adult rabbit was refractory. A young rabbit and a rat, in which there were grave accompanying affections, seemed more susceptible. A large guinea-pig showed spirilla in its blood for only two days succeeding the inoculation of a large dose of heavily infected blood. In it, as in three rats from whose blood spirilla, once present, finally disappeared, there appeared to have been a temporary increase in the number of the parasites, and dividing forms were seen.

Eight animals (seven monkeys and one rat) were infected with spirilla by the bites of ticks. Each animal was examined with negative result before the commencement of the experiment. Thirty other monkeys of the same species, caught in the same district and kept under the same conditions, were used for other experiments. Their blood was constantly examined and none was ever found to be infected with spirilla. In one monkey infection was apparently brought about by the bites of young ticks hatched in the laboratory from eggs laid by infected parents. If this was so, it might be assumed that ticks were not merely mechanical transmitting agents of the spirillum, but were alternative hosts in which developmental changes took place.

In the Congo Free State the human tick (*Ornithodoros monbata*) was found particularly along much traveled roads. Although plentiful in many of the Arab villages along the Congo between Kasongo and Ponthierville, they were quite unknown in the native villages an hour's walk inland. The rest-houses for native travelers were always the most infected. *Ornithodoros monbata* seemed to have come into the Free State by two routes; from the East Coast with the Arabs into the Oriental Province, and into the Cataract region with traders from the Portuguese territory to the south, where it had existed since Livingstone's time, at least.

In infested houses the ticks were found in the dust and cracks of mud-floors, particularly in dry places near the hearths, in bed-platforms, or immediately inside the door-sill just where the natives were accustomed to sit down. They might hide in the cracks and crevices of mud or grass walls, and even in the thatched roofs. They seemed to be largely nocturnal in their habits and certainly did not feed quickly enough to get much blood from any but a sleeping person. A big female might remain, firmly fixed, feeding on a monkey for two or three hours before it finally dropped off, as large as a cherry, distended and bloated with blood. Often while still feeding the whitish secretion of the Malpighian tubes was passed from the anus. The productivity of the females was certainly increased by large feeding. The number of eggs laid at a time seemed to vary greatly. Dissection showed that only a few eggs were matured at a time. Oviposition therefore went on slowly. On two occasions ticks were seen to be ovipositing during three days. In each instance only seventy eggs were laid. The largest number of eggs laid at one time was 139. The eggs adhered to one another as they were laid and looked, under a low power, not unlike bunches of glistening golden-brown grapes. The eggs hatched in about twenty days. Dutton and Todd noticed that the larva of *Ornithodoros monbata* was inactive. This was a new and interesting fact. In about seven days after oviposition the hexapod larva could be seen to be forming within the translucent egg-shell. At about the thirteenth day the egg-shell split, nearly always posteriorly, in the sagittal plane. Later the larval skin split and the eight-legged nymph threw off at the same moment both the egg-shell and its larval cast.

It was not determined for how long ticks might remain infective. Ticks caught at Nyangwé and kept without food were able to infect a monkey with spirilla one and three-quarter months later. Rats and ants were mentioned as natural enemies of *Ornithodoros monbata*. Rats ate the adult ticks with avidity, and ants carried off the young ones and eggs. In conclusion, Dutton and Todd stated that tick fever was clinically identical with relapsing fever, and that likewise it was caused by a spirillum which was probably no other than *Spirochæte obermeieri*. The disease could be transmitted by the tick (*Ornithodoros monbata*), and the transmission was probably not merely mechanical, but some development process was carried on in the tick.

**Pathogenic Ticks Concerned in the Distribution of Disease in Man.**—Mr. R. Newstead of Liverpool read this paper. He described the specific characters of *Ornithodoros monbata* and *Argas persicus*, and reiterated the facts described by Dutton and Todd concerning the life-history of *Ornithodoros monbata*.

Dr. L. W. Sambon of London said the investigations carried out by Dutton and Todd were of great interest. These observers had established the presence of relapsing fever in the Congo Free State, and had proved that the disease is propagated in that part of Africa by *Ornithodoros monbata*, a widely distributed tick belonging to the sub-family of the *Argasinæ*, and presenting life-habits very similar to those of the common bedbug. They had moreover suggested that the disease encountered by Dr. Livingstone and Sir John Kirk in the Zambesi valley, and attributed by the natives to the bite of *Ornithodoros monbata*, might be nothing more nor less than relapsing fever. This identity, suggested also previously by Ross and Milne, was probably correct, but no one could have guessed it solely from the scanty descriptions of the disease given first by Livingstone and Kirk, and more recently by Dowson and Daniels, especially as these authors mentioned violent purging and marked dysenteric symptoms, which are somewhat unusual in ordinary relapsing fever. If the "disease of Tete" on the Zambesi is a spirillum fever, then, most probably, the so-called "disease of Miana" in Northern Persia is likewise a spirillum fever. The disease of Miana is also transmitted by a tick of the sub-family *Argasinæ: Argas persicus*. And if spirillum fever is propagated by certain ticks in the Zambesi valley in the Congo Free State, in Uganda, and in Persia, it is very likely that in Egypt, in India, in China, and in Europe it is also transmitted by blood-sucking acarids or insects. Dutton and Todd's investigations prove the correctness of the views expressed by Tictin in 1897 with regard to the transmission of relapsing fever in Odessa by the common bedbug. In studying the various aspects of spirillosis we should consider that a parasite so widely distributed and fostered by different invertebrate pests in different countries, may be represented by a number of more or less distinct varieties. For my part, I believe we shall find this to be the case exactly in the same way as in trypanosomiasis. In South and Central America, in the West Indies, in Australia, in the Malay archipelago we know of ticks injurious to man. Spirillosis may be the cause in some instances, as, for example, in the case of *Argas turicata* in Mexico, but other pathogenic microorganisms may also be fostered and transmitted by ticks, such as *Piroplasmata*. Thus a new and very wide field of research is opened to investigators all the world over.

The speaker regretted that Dutton and Todd had reported only one doubtful case of infection by means of ticks hatched in the laboratory from eggs laid by infected parents, and not previously fed on men or animals suffering from the disease. Detailed and accurate information was very much needed concerning this interesting mode of transmission, which he considered to be the ordinary mode of transmission with ticks. Dutton and Todd, and Newstead had stated that the ticks while still feeding often passed

from the anus the whitish secretion of the Malpighian tubes. He wished to point out that a portion of this white excretory matter is formed within the cells of the ventriculus. Some of these cells go through a very peculiar process at the time of engorgement. They gradually elongate and take up the imbibed food, meanwhile they swell at their inner or distal end and become clavate, the elaborated food is then passed into the general body-cavity through the clavate portion and mixes with the blood of the tick; finally, the empty cell becomes globular and falls into the lumen of the ventriculus. A certain amount of excretory matter is left in the cell, and crystalizes or forms small concretions.

**Two Cases of Febrile Tropical Splenomegaly (Kala-azar) and a Suggestion.**—Sir PATRICK MANSON of London contributed a paper with this title. After describing two cases of kala-azar in which he had found the parasite discovered by Leishman and Donovan, he made the following remarkable suggestion: "The question that the Leishman body and that found by Wright in oriental sore are identical is an interesting, and may be an important, practical point. In tropical splenomegaly the Leishman body is found in spleen, liver, bone marrow, glands, intestinal ulcers, etc.; in oriental sore it occurs only in the sore; in the former case there appears to be a general infection, and certainly profound constitutional disturbance; in the latter the infection is strictly localized, and there is no clinical evidence of constitutional disturbance. But although there is no clinical evidence of constitutional disturbance in the case of oriental sore, there certainly must be some constitutional recognition of its presence, for it is well known, and the fact has been acted on for generations by the Jews of Bagdad, who anticipate the natural development of the disease—it might be on an inconvenient part of the face, where it would produce unsightliness or deformity—by the practice of inoculation on some less inconvenient region. They know that the disease so inoculated is protective. Assuming that the Leishman body of kala-azar and the corresponding germ of oriental sore, which are morphologically identical, are also specifically identical, and that, whereas the former is malignant in its course, the latter benign, it follows that the malignity of the kala-azar germ has been got rid of in some way or other. It has long been believed that oriental sore is a disease of countries in which the camel is a prominent domestic animal, and it has been maintained by some that the disease may be caught from the camel. These facts suggest to my mind that oriental sore may bear the same relation to kala-azar that vaccina does to smallpox, and that possibly the virulence of the kala-azar germ has been got rid of during its passage through the camel, just as the smallpox germ is deprived of its virulence by passing through the cow. This is conjecture, but seems to be a point worth working out, for should the conjecture turn out to be correct we may have ready to hand a means of preventing kala-azar."

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held May 4, 1905.*

DR. CHARLES L. DANA IN THE CHAIR.

**An Aid in the Diagnosis of Syphilis.**—Dr. N. B. POTTER presented two patients who had a condition at the base of the tongue which Virchow had described as being diagnostic of old syphilis and many clinicians were unaware of its value. He was not yet positive as to its value as an aid in diagnosis, but he was studying the subject and would report his findings at a later meeting. The condition was first described in Virchow's Archives in 1893. The mucous membrane behind the circumvallate papillæ felt velvety; whereas if any atrophy was present, as in syphilis, these glands were apt to be rather isolated, hard, quite small and sometimes large, but always hard. The ground substance of the membrane was apparently thickened but the microscope would show that it was thin. He thought it was quite characteristic of syphilis to find the glands in this situation isolated and hard, and believed it to be more or less diagnostic of old syphilis. One could not make such a diagnosis with the laryngeal mirror but by palpation.

**The Prognosis of Syphilis.**—Dr. S. POLLITZER read this paper. He said there were three factors which might be said to stand in a position of primary importance in determining the course of a given syphilis; (1) the intensity of the infection; (2) the resistance of the patient, and (3) chiefly the treatment. The influence of the first two factors could not readily be separated. As to the intensity of the infection only meager data were derived from the appearance of the initial lesion. It had been stated that extragenital chancres were usually followed by the more severe later lesions and, according to Fournier, this was especially true of chancres of the fingers. In considering the resistance of the patient to the infection he said we were on grounds almost wholly theoretical; we did not know upon what relative immunity depended. In general it might be stated though that syphilis was likely to run a more severe course in patients debilitated from any cause. As to the cutaneous lesions of the early period of syphilis, a mild course seemed to point to a mild course of the later syphilis so far as the skin was concerned, but it was noteworthy that often those cases that were particularly mild in the beginning, yielded a large percentage of the severe lesions of the central nervous system later. The occurrence of early pustular lesions pointed to a more severe course of the syphilis. All the superficial syphilides yielded a good prognosis as to themselves, and all responded more or less readily to appropriate treatment. The prognosis of syphilis invited earnest consideration only in connection with the occurrence of the later, the gummatous and sclerotic lesions, and the first question was "what are the chances of the development of tertiary lesions?" The classical notion that syphilis was a disease that always ran a certain fixed and fixed and definite course was true only in a small proportion of the cases. As a matter of fact in a large proportion of the cases of syphilis to-day no symptoms beyond the chancre and the early cutaneous lesions ever make their appearance and this cessation, *quasi* abortion, of the disease was due in great part to prompt and energetic treatment; but it was undoubtedly true that syphilis was often a self-limited disease. Diday's experiments upon 43 cases of syphilis, withholding all medication, showed 60 per cent. of spontaneous cures; this was probably too high a percentage because they were not all under observation a sufficient length of time. In what proportion of cases, as we see them, may tertiary accidents be expected? Mauriac in Paris, who had examined into this question very thoroughly, concluded that tertiary lesions developed in not less than 5 per cent. nor more than 20 per cent. of all cases of syphilis, and that 10 per cent. to 15 per cent. was nearer the truth. In a record of 10,277 cases of tertiary lesions, made by Fournier, Ehlers, Hjelman and Haslund, gummata of the skin subcutis and the visible mucosa occurred in 4,902 (47.7 per cent), leaving 5,173 (52.3 per cent.) for the lesions of the viscera including the bones. Bearing in mind the estimate of 15 per cent. of tertiary lesions in all cases of syphilitic infection, one must conclude that in about 7 per cent. of the cases, cutaneous, etc., gummata occurred, and in about 8 per cent. visceral lesions depeloped. These figures could only be taken as a crude approximation to the truth. It was probable that the proportion of tertiary lesions of the viscera taken from the statistics of syphilographers was far too low, and that syphilis of the viscera occurred in considerably more than 8 per cent. of all cases of syphilis. The relation of syphilis to diseases of the heart and arteries was being better understood, and though it was often difficult to separate the influences of syphilis from other causes in the production of diffuse and nodular sclerosis, obliterating endarteritis, hyaline and amyloid degeneration, with all their serious secondary effects in vital organs there seemed little doubt that syphilis played an important rôle in the causation. The coarser syphilitic

lesions of the heart were well known, but that the heart was affected early in syphilis seemed not to be so generally understood. Syphilitic lesions of the lungs were probably far more commonly overlooked than recognized. The disease occurred in the form of gumma, which showed relatively little tendency to break down, diffuse infiltration and fibroid peribronchitis and periarteritis. Of all the internal organs the central nervous system seemed to suffer most frequently from the later lesions of syphilis. In Fournier's large statistics 21 per cent. of syphilis of the nervous system was recorded, not counting the cases of tabes and paresis. About 3 in every 100 cases of syphilitic infection develop nerve lesions. The ocular palsies, the milder forms of meningitis, even the circumscribed syphilitic tumors of the brain and cord in the majority of cases were amenable to treatment and might disappear without leaving a trace. Reliable data on which to estimate the proportion of syphilitics who become tabetic or paretic were still lacking. What shall be the answer given to the syphilitic who consults on the question of marriage? From the vast accumulated experience of many generations, he said one might deduct certain rules for our guidance in this momentous question. They were (1) The syphilitic should not marry till at least three years after his infection; (2) the syphilitic should not marry who had not undergone a thorough course of treatment with mercury; (3) the syphilitic who had observed the first two postulates still should not marry till a period of a year had elapsed without the appearance of any symptoms of his disease.

Dr. R. W. Taylor said that when a patient had been informed that he was syphilitic he immediately began to question the surgeon as to his chances in the future and inquire whether he could be thoroughly cured, how long it would take to cure him, would he suffer very much, would he be as good as he was before he was infected, and could he entertain the thought of marriage, and would his children be healthy. This showed the necessity of a thorough knowledge of the prognosis of syphilis. It was, therefore, important to determine what the nature of syphilis was and to acquaint ourselves with the course of the infection in healthy and diseased subjects, and of the influence of therapeutics upon this infection. From statements made it seemed warrantable to conclude that there was a well-marked uniformity in the infectious quality of the virus, no matter from whom it might be derived, and that this poison might produce in some subjects a mild and in others a severe form of syphilis; therefore, the benignity or severity of syphilis was determined by the condition of the individual. Both mild and severe grades of syphilis might follow small initial lesions. It was only partially true that large and deep primary lesions invariably lead to severe forms of infection. It was not fully warranted to state either that ulceration, phagedema and gangrene, attacking the initial lesion, was an ominous sign of a severe attack of syphilis. Destructive ulceration, or any form of gangrene attacking the initial lesion, was always the result of contamination with pyogenic microbes. The view claimed by some authors that extragenital chancres were the forerunners of severe syphilis was not borne out by any extended investigation. Fortunately, syphilis in the great majority of cases was contracted by young men between twenty and forty years of age in whom the vital processes were active and whose health as a rule was good. According to Dr. Taylor's observations syphilis was less severe to-day than it was thirty years ago, and this diminution was largely due to improved methods of treatment, to better sanitary and nutritive conditions, and to the greater attention paid to cleanliness and antiseptics. Again, he believed that in many people a moderate condition of immunity against syphilis existed, due to changes in the tissues and in the blood induced by syphilis in more or less remote ancestors. Syphilis in healthy persons, as a rule, ran a mild course, and its poison was eliminated from the system if active treatment be instituted at the proper time, and a cure would result in two or three years. In America syphilis in women ran about the course that it did in men, but the female sex was much less frequently attacked by cerebral and cerebrospinal syphilis than men. Perhaps the greatest drawback in the treatment of syphilis in the poor was to establish in their minds a realizing sense of the gravity of the effection. Precocious malignant syphilis usually began in the severer forms of the disease in which ulceration attacked the various lesions. Malignant syphilis was undoubtedly a rare and peculiar form of the disease and its chief characteristic was that it was essentially a secondary condition and in no way associated with tertiary syphilis. In these patients the nervous affections were not due to gummatous deposits, but rather to the round cell infiltration around the vessels, chiefly of the membranes of the brain. Malignant syphilis was due to lack of resistance on the part of the individual to the severity of the infection. By far the most potent cause of tertiary syphilis was absence or insufficient treatment in the secondary stage. One of the most formidable complications of syphilis was tuberculosis and this destructive and deadly symbiosis was seen in the secondary and in the tertiary periods. In malarial subjects the course of the disease was frequently severe. Bright's disease was a factor of much gravity in patients also infected with syphilis. Diabetic subjects were commonly profoundly influenced by syphilis, as well as those suffering from various blood states, such as scurvy, the hemorrhagic diathesis and hemoglobinuria. Many other diseases unfavorably influenced the course of the infection. Upon the integrity of the patient's blood vessels hinged in a large degree the greater or less severity of syphilis and, therefore, in advanced life with its accompanying arteriosclerosis, syphilis became a severer affection. Besides vessel changes, visceral lesions, general debility, an unstable condition of the tissues, and the systemic morbid effects produced by vicious habits and indulgences, were undoubtedly factors of gravity in syphilis of advanced age. Early, efficient, painstaking and prolonged treatment was most essential in all cases of syphilis, and by it the course of the disease in the young and the aged could be much modified, could be rendered mild, and in most cases a cure would be produced.

**Lesions of the Viscera.**—Dr. I. Adler considered this part of the topic and said that the prognosis in visceral syphilis depended largely on the localization of the lesion. A large lesion affecting the liver might not be productive of grave symptoms or menace life; while a very small lesion of the heart muscle, causing absorption and the deposition of fibrous tissue, would necessarily impair that organ and might lead to a fatal result. The early recognition and early treatment of the disease was very important and in this respect many advances had been made. The only forms commonly recognized were the hard gumma and aneurism. Heart syphilis, according to the Continental physicians, was nearly as frequent as syphilis of the nervous system. In many instances of syphilis, even without clinically recognizable heart lesions, there are heart changes involving particularly the small blood vessels, or a perivasculitis affecting the arteries, as well as the veins and capillaries. Here there was a round cell infiltration and an inflammation of the perivascular spaces. These he said could be demonstrated at an early stage. The physician should not look for murmurs, but there would be noted a little irregularity in the heart sounds, a reduplication usually of the second sound and a slight friction. These symptoms were quite evanescent but always were associated with slight objective symptoms and slight temperature. Many obscure cases of endocarditis found during the middle period of life and young persons presented valvular changes which could have been avoided if the slightest lesions had been recognized and treated in the course of a syphilitic affection in the early stages. From this it followed that the physician should not consider his patient cured if palpable symptoms and external symptoms had disappeared; only should they be considered as cured when those heart signs and other features of syphilis had permanently disappeared.

On the other hand it was the duty of the clinician who investigated cases with heart disease, whether valvular or of the heart muscle, to consider syphilis as one of the most prominent factors, and where there was no distinct etiology, always to have syphilis in his mind and to treat the patient accordingly. He had no doubt that beneficial results would follow the use of the iodides in old syphilitic lesions of the heart, and what he said regarding the heart held good for lesions in the kidneys. Many cases of chronic interstitial nephritis were originally syhpilitic and could have been prevented by the early recognition and treatment of the disease.

**Syphilis of the Nervous System.**—Dr. M. Allen Starr said that the number of diseases of the nervous system traceable to syphilis was very large, but there were some tissues which seemed to be exempt, notably the peripheral nerves. He said he had never seen a single case of multiple neuritis of syphilitic origin. It was the central nervous system that was commonly affected by syphilis, and he wished to confine himself to such diseases of the brain and spinal cord. In determining the prognosis of these various lesions one should sharply note the difference between the effects of gummata and the effects of arterial disease. The prognosis in gumma exudations within the brain and meninges, or the base of the brain, or in or around the spinal cord, he believed to be a fairly good one, and he reported two cases which entirely recovered under the employment of antisyphilitic treatment. There were many instances of recovery from very serious lesions when the lesions were of the nature of a gumma. But when syphilitic disease was located in the blood vessels it was different; here the prognosis was made not on the mere accident that syphilis was the cause of the endocarditis, but upon the fact that such cases of endocarditis leads to an obliteration and cutting off of the blood supply and the formation of thrombi in the vessels; in such cases it made no difference whether the condition was syphilitic in origin or not. The importance of recognizing the element of syphilis in the production of functional nervous diseases should be borne in mind; also in the causation of certain forms of epilepsy, especially those forms that develop after the age of 35 or 40; here the epilepsy might be traced to some form of syphilis of the brain, such as gumma, or infiltration, or arterial disease. Therefore, in such cases, the bromide treatment should have combined with it mercury and the iodides. He believed the good results that had been obtained from the Brown-Sequard mixture was not alone due to the bromides but to the iodides. He referred to a peculiar type of pain, neither myalgic nor neuralgic, which seemed to have some definite connection with syphilis. There were peculiar types of headache not distinctly unilateral, also pains along the spine, in the joints, and in various other locations, none presenting typical features of myalgia or neuralgia, which he believed could be traced to syphilis. A characteristic feature of these pains was the periodicity.

**Prognosis of Tabes and Paresis.**—Dr. B. Sachs said that cases of tabes and general paresis that he had seen in private practice, in which he had made careful inquiries regarding the previous treatment of syphilis, had been thoroughly treated. The manifestations of the nervous lesions varied greatly in spite of thorough early treatment. In the history of some cases where there were severe nervous symptoms he had found that there was given a history of soft chancre as often as of hard chancre. The period when the nervous manifestations of syphilis appeared varied although it was usually believed that they did not appear until after a long time had elapsed. Some of the severe forms of spinal and brain syphilis appear from two to three years after the initial lesion. The statistics showed that all cases of syphilis of the central nervous system appear within the first three years after infection. He said all neurologists were agreed as to the specific etiology of both tabes and general paresis; at the same time the consensus of opinion was that, in every case, there were other predisposing causes of importance, such as traumatism, alcoholism, excessive worry and work, etc., indispensable factors which followed in the wake of a syphilitic infection. The prognosis of tabes was a serious one. At the present time one saw fewer cases of extreme tabes because of the earlier recognition and earlier treatment. In the treatment of tabes the iodides alone were insufficient; if there was one specific it was mercury. What was said regarding tabes applied equally as well to dementia paralytica. These diseases could not be cured, but proper treatment, instituted early, could arrest the course of these diseases. The importance and value of thoroughly antisyphilitic treatment in these cases should not be underrated.

**Relations of Syphilis to Marriage and Heredity.**—Dr. Prince A. Morrow read this paper. He considered the prognostic significance of syphilis first in regard to the risks to the prospective husband and second the risks to the wife and the danger to offspring from her infection. Where the question of marriage was concerned the physician was apt to overlook the possible dangers to the health of the husband from his disease. It might so affect his health as to incapacitate him as the support and head of a family. It was a peculiarity of syphilis that its most dangerous and deadly consequences were the late manifestations. Grave lesions on important organs resulting in hemiplegia, paraplegia, general paralysis, etc., developed in syphilis characterized by an initial benignity. There was nothing more difficult and uncertain than forecasting the future of a given case of syphilis. In many cases valuable prognostic indications might be drawn from the earlier manifestations of the disease which pointed to the involvement of the nervous system as the localization of specific lesions in the ocular apparatus, the occurrence of iritis, paralysis of the muscles of the eye, etc. In regard to the contamination of the wife Dr. Morrow said that when the syphilis was recent and active contamination was practically certain, infection might occur when the husband had upon his person no contagious lesion. The risk of infection to the wife was based upon the duration of the contagious and transmissive periods. Clinical observation showed that the contagious activity of syphilis was markedly attenuated and finally extinguished by time and treatment. The time limit could not be exactly stated, as it varied in different cases. It was usually twelve to eighteen months after the completion of the secondary stage and sufficient specific treatment. The arbitrary designation of two and one-half to three years was medically an error and socially a danger. The prognosis of syphilis in relation to heredity was much more unfavorable when the wife became infected. The corrective influence of time upon syphilitic heredity was less marked since the hereditary influence might be manifested long after the disease had ceased to be contagious; this was especially true of maternal heredity. The preventive influence of treatment upon syphilitic heredity was more marked but less permanent. If the syphilitic parent was under the active influence of mercury at the time of impregnation a healthy child might result; but if treatment was suspended the next child might be syphilitic. After four years' treatment the transmissive qualities were practically extinguished. Dr. Morrow did not think that marriage had a favorable influence upon the syphilitic, as the sexual excesses, not uncommon in early married life, aggravated nervous symptoms and might determine serious implication of the brain and cord.

Dr. William H. Thomson referred to the early recognition of cardiac involvement in syphilis and said that he had been struck by the clinical symptoms in one or perhaps two cases, namely, the heart in an apparently strong man would become weak and irregular and the patient was given to repeated sighing. In a few cases seen in hospital practice giving the clinical signs of myocarditis, a history of syphilis within two years was elicited by careful questioning of the patient.

## Books Received.

*While the* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

LES KYSTES HYDATIQUES DU FOIE. Par le DR. F. DÉVÉ. 12mo, 196 pages, paper. F. R. de Rudeval, Paris.

SELECT METHODS IN FOOD ANALYSIS. By HENRY LEFFMANN, A.M., M.D., PH.D. and WILLIAM BEAM, A.M., M.D., F.I.C. Second Edition. 8vo, 396 pages illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $2.50 net.

THE DIAGNOSIS OF DISEASES OF WOMEN. By PALMER FINDLEY, B.S., M.D. Second Edition. 8vo, 588 pages, muslin, illustrated. Lea Brothers & Co., Philadelphia. Price. $4.75 net.

A SYSTEMATIC TREATISE ON MATERIA MEDICA AND THERAPEUTICS WITH REFERENCE TO THE MOST DIRECT ACTION OF DRUGS. By FINLEY ELLINGWOOD, M.D. Fifth Edition. 8vo, 811 pages, muslin. Chicago Medical Times Publishing Co., Chicago.

HEALTH AND DISEASE IN RELATION TO MARRIAGE AND THE MARRIED STATE. By various authors. Translated from the German by J. Dulberg, M.D. Volume 2. 8vo, pp. 481-1257, muslin. Rebman Company, New York.

OUTLINES OF INORGANIC CHEMISTRY. By Prof. FRANK AUSTIN GOOCH and CLAUDE FREDERIC WALKER. 8vo, 514 pages, illustrated, muslin. The Macmillan Co., New York. Price, $1.75 net.

MANUAL OF CLINICAL REPERTORY OF A COMPLETE LIST OF TISSUE REMEDIES. By Dr. MED. ERIC GRAF VON DER GOLTZ. 16mo, 244 pages, muslin. Boericke & Tafel, Philadelphia.

THE ROLE OF MODERN DIETETICS IN THE CAUSATION OF DISEASE. By J. SIM WALLACE, M.D., D.Sc., L.D.S. 8vo, 87 pages, muslin. Bailliere, Tindall & Cox, London, England.

REPORT OF THE COMMISSIONER OF EDUCATION FOR THE YEAR 1903. Vol. 2. 8vo, pp. 1217-2511, muslin.

A MANUAL OF PRACTICAL HYGIENE. By CHARLES HARRINGTON.. M.D. Third edition. 8vo, 793 pages, illustrated, muslin. Lea Brothers & Co., Philadelphia. Price, $4.25 net.

DIE KRANKHEITEN DES VERDAUUNGSKANALS. (OESOPHAGUS, MAGEN, DARM). Von Dr. PAUL COHNHEIM. 8vo, 247 pages. S. Karger, Berlin, Germany.

THE SURGEON GENERALS OF THE ARMY OF THE UNITED STATES OF AMERICA. By JAMES EVELYN PILCHER, M.D., Ph.D., L.H.D. 8vo, 114 pages, illustrated, muslin. The Association of Military Surgeons, Carlisle, Penna.

THE COMPLETE KANO JIU-JITSU. By H. IRVING HANCOCK and KATSUKUMA HIGASHI. 8vo, 526 pages, illustrated, muslin. G. P. Putnam's Sons, New York.

THE SANITATION OF A COUNTRY HOUSE. By Dr. HARVEY B. BASHORE. 12mo, 103 pages, illustrated, muslin. John Wiley & Sons, New York.

A TEXT-BOOK OF PHYSIOLOGY, NORMAL AND PATHOLOGICAL. By WINFIELD S. HALL, PH.D., M.D. Second Edition. 8vo, 795 pages, muslin, illustrated. Lea Brothers & Co., Philadelphia.

---

**The Terms Bradycardia and Tachycardia** are very bad, according to Dr. G. A. Gibson, writing in the *Edinburgh Medical Journal*. The early Greek writers, he says, employed the word βραδύς in the sense of the Latin *tardus*, meaning of any action that it took place *slowly*, while they used the phrase ταχύς as the equivalent of *celer*, implying that any event occurred *quickly*. The real term for a pulse which has a low rate is ἀραιός, equal to *rarus* or *infrequens;* for a pulse of high rate the classical name is πυκνός, which is the equivalent of *crebor* or *frequens*. The consideration of such medical terms, Dr. Gibson says, inevitably recalls the remark of Anatole France: "Ces maux, effroi de l'homme, ont des noms, effroi du philologue."

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 19, 1905:

| | Cases | Deaths |
|---|---|---|
| Measles | 119 | 5 |
| Diphtheria and Croup | 117 | 19 |
| Scarlet Fever | 41 | 3 |
| Smallpox | ..... | ..... |
| Chickenpox | 14 | ..... |
| Tuberculosis | 463 | 115 |
| Typhoid Fever | 252 | 25 |
| Cerebrospinal Meningitis | 16 | 16 |
| Typhus Fever | ..... | ..... |
| Yellow Fever | ..... | ..... |
| Cholera | ..... | ..... |
| Totals | 1022 | 183 |

**Signification and Importance of an Axillary Temperature of 98.6° to 99.5°.**—Vittorio Levi tells us that, although a temperature of 98.6° to 99.5° is usually considered normal, facts observed by him during a long practice have led him to the following conclusions: A temperature from 98.6° to 99.5° must always be considered above the normal; even 98.6° is to be suspected; temperature of 97.7° to 98.6° is rather to be considered normal; the temperature usually found in a normal individual in the axilla or the inguinal region is 97.7° or 98°. While he combats the objections which might be made to these conclusions, the author believes these considerations to be of value in prognosis, in diagnosis, in treatment and finally to exclude the possibility of simulation by the patient.—*Rivista Critica di Clinica Medica*.

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service during the week ending August 12, 1905:

SMALLPOX—UNITED STATES.

### TWO CASES OF FUNCTIONAL STRABISMUS.

By D. B. St. John Roosa, M.D., LL.D.,

New York.

Professor of Diseases of the Eye and Ear in the New York Post-Graduate Medical School.

The following cases of strabismus present conditions very seldom found in this abnormality:

Case I.—*Functional convergent strabismus, said to have supervened on cerebral symptoms; Panas operation; excessive effect, for a few days; recovery; intermittent strabismus, with double vision; complete cure.* Elizabeth D., aged 11, was first seen by the writer on the 3d of April, 1901. The mother, a highly educated and intelligent woman, gave the child's history as follows: On the 2d of the preceding September, the patient had symptoms which the physician in charge called "cerebral meningitis." Convergent strabismus and double vision were very marked symptoms. She recovered from the other head difficulties, but she continued to have functional strabismus, squinting by preference with the left eye. Her vision was 20/30 + in the right and left eyes, with faculative hypermetropia of 1 D. There were three-quarters of a diopter of corneal astigmatism in the right eye, and 1 diopter in the left.

Treatment for the correction of the squint by glasses, previously undertaken, having been ineffectual, an operation was advised, and the next day both interni were stretched and divided, under ether, according to the method of Panas. On the 9th of April there was an over-effect. The patient had insufficiency of the interni and crossed diplopia, as well as marked divergence. The stereoscope was used by the patient, but on the 12th of April, eight days after the operation, while there was no apparent divergence, there was crossed diplopia at 20 feet. She was given plus cylindrical glasses, half a diopter, axis 90°, for reading only. On the 28th day of May there was an upward squint of about two lines—in the left eye and vertical diplopia. There was no convergence or divergence. The very next day there was no double vision whatever, and no displacement upward of the eye. For some time the double vision occurred every other day, but in November it was irregular, and sometimes for only half a day. The child would tell her mother that her eyes were going to cross, and then the manifest upward squint would occur. One year after the operation the condition continued to be the same,—that is to say, there was, at irregular intervals, an upward squint of the left eye, with vertical diplopia. She usually had binocular single vision. The vision was 20/20 with her glasses. This intermittent deviation of the eye led to a correspondence with the family physician, in a neighboring city. The child's nutrition was looked after most carefully, and quinine was administered for a time, but having no effect on the intermittent squint, its use was finally abandoned. The cylindric glasses were constantly worn. In November of this year the patient came to my office with the eye diviated upward, and with vertical diplopia. In a few moments, after turning her head in various directions, the upward squint and double vision disappeared, and the eyes became parallel. The squint did not then occur every other day, and lasted a much shorter time.

Without any special treatment, all the attempts to effect a cure, except the use of the stereoscope and correcting glasses, having been abandoned, the intermittent strabismus ceased in the autumn of 1903. In March, 1905, the patient was examined by myself again, and there was absolute parallelism, no double vision, the child constantly wearing cylindric glasses to correct the astigmatism. The measurement of the corneal astigmatism, four years after the first examination, showed an increase on one side. The right cornea, which had been three-quarters of a diopter, measured 1.25, and the left remained the same, that is, 1 diopter. The patient continued to wear glasses constantly.

*Remarks.*—There has always been a doubt in the writer's mind whether the child ever had cerebral meningitis, but that a sudden occurrence of functional strabismus, with double vision, may have caused all the cerebral symptoms. These symptoms might well have supervened on such an occurrence. The outcome of the case was entirely satisfactory, and I think may fairly be ascribed to the operation, with the subsequent correction of the error of refraction. Yet the etiology of the sudden outbreak of strabismus, with double vision, while the refractive error was the same in both eyes, is obscure.

Before leaving this case, the principle of the Panas operation for strabismus may profitably be restated. The operation of stretching the muscles and separating them from their attachment, is not intended to have any effect on their power as measured by prisms, but is simply to remove a spastic condition, which is assumed to exist, and to put the eye in a state to be properly corrected as to its refraction, by glasses. The writer also calls attention to the fact that in this patient, in accordance with the views now strongly established in his mind and in that of many of his colleagues, no attempts were made to measure the power of the muscles. Indeed, I may say that I do not believe it is possible to grade the effect of the operation as Graefe thought, and as seems to be quite generally believed by writers of the present time—by any method of operating. So long as no undue violence is done, the muscle being separated and not cut, stretched, not torn, a condition is produced which will render the case one simply for the adjustment of glasses. I have long held in common with many of my fellow ophthalmologists that the operation of strabismus should only be performed when, after a fair trial, it is impracticable to cure the case without operation.

Case II.—*Functional convergent strabismus and amblyopia ex anopsia, cured by glasses; exclusion of the amblyopic eye at intervals, and the use of the*

*stereoscope*. The second case was that of a boy, W. B., four and a half years old, with convergent strabismus. I saw him first on the 15th of May, 1894. He had functional convergent strabismus, of three lines, and one diopter of corneal astigmatism in each eye, and also three diopters or more, of hypermetropia, as measured by the ophthalmoscope. He did not read, and his vision could not be accurately noted on his first visit. He was wearing a + 2.50 glass for each eye, which had been prescribed for him with a view of curing the squint. The glasses were reduced in strength to those of one diopter. He was not only directed to wear them all the time, but also to exercise the vision of the deficient eye, according to the method of Javal. In 1896, it was determined positively that his vision was 20/30 in the right eye, and 20/100, in the left eye. At the latter end of the year, it became 20/70 in the left eye. He was then about seven years of age, his corneal astigmatism was corrected, and his hypermetrophic glasses reduced in strength. In 1897, the strabismus continued, and his vision remained the same. In 1898, about four years after he was first seen, there was no strabismus while he was wearing glasses. The vision of his left eye had improved to 20/50, and at the end of 1898 he could read No. 1 Jaeger with that eye with some difficulty. The improvement continued. In 1902 his good eye improved to 20/15, his left became 20/20, and he could read No. 1 Jaeger with ease. In 1903 the improvement still continued, his vision being 20/15 in each eye. In 1905 he remained the same.

*Remarks.*—The drilling of this patient was very thorough. He was systematically made to keep his good eye covered while eating his meals, and also to read at certain times of the day, with his good eye covered, exclusively with his deficient eye. It would have been impossible with a neglected or incompetent mother to have achieved this result. It may be said to have taken about eight years to accomplish all this. The patient has grown to be a strong and vigorous boy, of about thirteen years of age, with one eye quite as good as the other, with no strabismus, but he still wears his correcting glasses. So many doubts are cast upon cases of this kind, that every positive contribution is certainly of value, and for this reason this case is published. It certainly should stimulate earnest work on these lines.

20 East Thirtieth Street.

## THE FOOD FACTOR IN URICEMIA.

By FRANCIS HARE, M.D.,

London.

Late Consulting Physician to the Brisbane General Hospital, Visiting Physician to the Diamantina Hospital for Chronic Diseases, Brisbane.

In a recent article[1] in this journal, it was argued concerning acute articular gout: (1) That there is primarily hyperpyremia, that is, a humoral condition implying an ultra-physiological or pathological accumulation in the blood of unoxidized carbonaceous material derived from the food supply; (2) that continued hyperpyremia involves progressively increasing uricemia through inadequate renal excretion of uric acid; (3) that ultimately a portion of the uric acid retained in the blood becomes deposited extravascularly; (4) that when this deposit occurs in the sensitive structures of a joint, arthritis occurs; (5) that such arthritis when sufficiently acute, involves distinct pyrexia; (6) that such gouty pyrexia implies a distinct increase in the rate of combustion by the nitrogenous tissues of the organism; (7) that such increase of combustion succeeds, in the course of the attack, in dispersing hyperpyremia; (8) that the dispersion of hyperpyremia terminates the renal disability and permits of free excretion of uric acid by the kidneys; (9) that the free excretion disperses the uricemia; (10) that the dispersion of the uricemia fully restores the solvent power of the blood for uric acid; (11) that the restoration of such solvent power permits the reabsorption of the articular uratic deposits; and (12) that such reabsorption permits resolution of the arthritis and leads to the practically complete restoration of the functions of the joint. Thus acute articular gout becomes a recurrent acarbonizing process, dependent on, and adapted to disperse, hyperpyremia and secondary uricemia—it becomes, in more general terms, an ultra-physiological reinforcement of inadequate physiological function, and in the strict sense of the term, a conservative*—though not invariably a salutary—pathological function.

This view explains the self-curative influence of the arthritis and the subsequent period of immunity from arthritis. It also explains the fact long noticed, though somewhat obscured of late years, that an acute attack of gout is commonly succeeded for some considerable time by complete freedom from all those heterogeneous symptoms—dyspeptic, bilious, cutaneous, nervous, psychical, etc.—which are apt to precede and lead up to the attack, which are promptly dispersed by the attack, and which consequently have been regarded quite naturally as manifestations of irregular, abarticular, concealed, or suppressed gout. But later[2] I shall bring a considerable mass of evidence to show: (1) that the heterogenous symptoms referred to have no necessary connection with gout, using the word in the restricted sense to denote uratic arthritis or other inflammatory processes *depending on extravascular deposition of urates;* (2) that they have nothing but an incidental connection with uricemia; but (3) that they all depend upon the hyperpyremia, the fundamental factor of the uricemia and therefore of the arthritic attack.

This view explains also the natural clinical history of chronic articular gout. The chief salutary feature in acute articular gout is the pyrexia, or rather the increase of combustion implied in the pyrexia; and the pyrexia depends upon the intensity of the arthritis. In very chronic articular gout, there is practically no local inflammatory reaction (Garrod), and consequently practically no pyrexia. Hence it is easy to understand that the hyperpyremia will remain unrelieved, that the uricemia will persist, and that the articular uratic deposits will not only not undergo reabsorption, but will tend to increase progressively. All this occurs in chronic gout. The persistence of the hyperpyremia may be inferred from the persistence and accentuation of the heterogeneous symptoms usually referred to irregular gout. The persistence of the uricemia is guaranteed experimentally by Garrod, who says: "In very chronic gout, the blood, even in the intervals between the exacerbations, was always discovered to be rich in uric acid."[3] And the persistence of the uratic deposits may be observed at the bedside and in the post mortem room; as Garrod points out, "chronic gout seldom continues in one locality for any length of time without giving rise to serious and permanent changes of structure, consisting either in the production of partial or complete ankylosis of the joint or the formation of the so-called chalk stones, either around the articulation or in other parts of the body."[4] Thus chronic articular gout tends to progressive deterioration, constitutional and local, be-

* The term conservative is here used in a somewhat teleological sense to signify salutary in intent, though not necessarily in effect.

cause it lacks the conservative feature of pyrexia; the absence of pyrexia depends on the absence of acute arthritis; and the absence of acute arthritis may reasonably be ascribed, in some cases at least, to an unirritability of the joint tissues acquired through long recurrent irritation. In short, chronic articular gout may be regarded as a worn-out pyrexial acarbonizing process.

The weak point in the hyperpyremic theory of gout, is the hitherto unsupported assumption that the structurally and functionally normal kidney finds it difficult to extract uric acid from overcarbonized blood (hyperpyremia). It may be at once admitted that no explanation as to the "how" or "why" of this disability can be offered. But it is by no means necessary to explain a fact in order to accept it. And in the present instance, it can, I think, be shown by sufficient independent evidence, not only that hyperpyremia and the dispersion of hyperpyremia involve uricemia and the dispersion of uricemia respectively, but also that within the domain of pure physiology, the elimination of uric acid from the blood depends inversely upon the degree of pyremia.

*Variations in uricemia and uric acid excretion depending on pyremic conditions.*—Daily pyremic fluctuations. It has been argued that there is throughout the twenty-four hours a tendency to inverse fluctuation between pyremia and the rate of combustion. Hence the uric acid excretion would tend to fluctuate directly with the temperature of the body, which we have seen is a fair index of the rate of combustion. This anticipated parallelism is clearly seen on comparing the two subjoined tables:

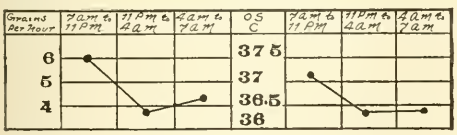

CHART 1.—Showing daily fluctuations in uric-acid excretion. (From Haig's "Uric Acid in Disease," 1897.)

CHART 2.—Showing the corresponding daily fluctuations in the rate of combustion. (Constructed from Liebermeister's observations on temperature in Schafer's "Textbook of Physiology," vol. 1, p. 800.)

The comparison is given for what it is worth. Undoubtedly the fluctuation of uric acid excretion, especially the high output between 7 A.M. and 11 P.M., depends to some extent, if not mainly, upon the introduction with the food of uric acid-forming material. (This will be considered later.) Still the fluctuations have probably a bearing on the pyremic factor.

*Menstrual pyremic fluctuations.*—On the view that the menstrual flow constitutes one form of carbonaceous expenditure, there is probably a normal tendency (slight) to hyperpyremia just before and at the onset of menstruation, a dispersion of this tendency thereafter. Conformably Haig infers from numerous quantitative analyses that during menstruation there is "a fluctuation in the excretion of uric acid, a diminished excretion or retention just before or at the beginning of the period, followed by a corresponding pus excretion during the period and just after its termination."[5]

*Pyremic variations due to physical exercise.*—Physical exercise greatly increases the rate of combustion: it tends therefore to disperse hyperpyremia and to reduce pyremia. And it has been shown that physical exercise markedly increases the output of uric acid (Ewart[6]). Levison gives the results of active muscular exercise in the saddle on two occasions. On the first occasion the uric acid excretion rose from .6 gm. to .981 or .985 gm.; on the second, to 1.089 gm.[7] Haig's experiments show a similar and an equally constant result.[8]

It is extremely important to take notice of the fact that the increase of uric acid excretion which follows exercise is merely temporary. Duckworth points out that the exercise which increases uric acid excretion is *unaccustomed* exercise.[9] And Robert Hutchinson says: "When a man of sedentary habits takes exercise, the excretion of uric acid is increased for the first day or two, but if the exercise be continued daily, the increase is not maintained."[10] The importance of this observation lies in the proof it affords that the increase of uric acid excretion which follows exercise, represents, not an increase of uric acid production, but the releasement of a prior retention depending on hyperpyremia or a tendency thereto. This conclusion is important from the standpoint of practical therapeutics; for there can be no doubt that systematic physical exercise is one of the best of all means for averting a tendency to uric acid retention.

*Pyremic variations due to pyrexia.*—Pyrexia tends to disperse hyperpyremia and to reduce pyremia through material increase in the rate of combustion; this has been already argued. But in most cases, probably to some extent in all, pyrexia operates to the same end through decrease in the carbonaceous income from anorexia and impaired digestive power. Hence the increased renal excretion and consequent dispersion of preexisting uricemia which accompanies and succeeds the acute gouty pyrexia. But pyrexia of many, probably of most, kinds is similarly associated. Bristowe says that fever may increase uric acid excretion twofold.[11] Schultze was making a series of quantitative analyses on his own urinary excretion. "Fever and malaise accompanied by headache appeared one day. . . In twenty-four hours, 37.08 gm. urea and 1.2687 gm. uric acid were excreted; consequently while the excretion of urea was nearly normal, the excretion of uric acid was almost as much increased as by a large quantity of animal food."[12] And many other confirmatory experiments could be quoted.

It is extremely important to take notice of the fact that the increase of uric acid excretion which follows the onset of fever, just like the increase which follows physical exercise, is merely temporary. Haig, speaking of the influence of fevers on uric acid excretion, points out "that the blood and urine are most completely cleared of uric acid during the first few days of fever."[13] Confirmatory of this statement are the facts that Garrod could never find uric acid in the blood during rheumatic fever; and that "in the examination of ten patients who suffered from typhoid fever, no uric acid was found during the fever" in the blood (Von Jaksch[14]). Again confirmatory are the facts that in one case of typhoid which had entered on the non-febrile stage, some uric acid was found in the blood (Von Jaksch); and that in a case of ague, uricemia was detected for the first time after the temperature had fallen (Haig.[15]). It is, I think, fair to conclude that the increase of uric acid excretion which is observed at the onset of pyrexia, represents the releasement of a prior retention in the blood; that during the continuance of most pyrexias, uricemia is precluded; but that during convalescence, when the exaggerated combustion has ceased, possibly to be replaced by a reactionary retardation of combustion, and when the carbonaceous income from the alimentary canal is again rising, then uricemia from deficient renal excretion once more becomes possible.

There is, however, at least one form of pyrexia

in which uricemia is usually present throughout. Von Jaksch found uric acid constantly present in considerable quantity in five cases of pneumonia even during the febrile stage.[16] Possibly the uricemia in pneumonia is due to retention, and the retention to the accumulation in the blood of the fully oxidized carbon compound, carbonic acid.

*Hyperpyremia due to plumbism.*—It has been argued that plumbism conduces to hyperpyremia through impaired decarbonization, katabolic and anabolic; and plumbism is almost always associated with uricemia and diminished excretion of uric acid in the urine. In nine cases of gout-free plumbism, Garrod found uric acid in the blood of all but two, and mostly in considerable quantities.[17] The decrease of uric acid excretion was clearly shown by the medical use of lead. In one case four-grain doses of lead acetate thrice daily reduced the average daily excretion from 6.5 grs, to 3.65 grs., and again to 2.66 grs. In another two grain doses thrice daily reduced the daily average excretion from 6.76 grs. to 5.92 grs. Garrod concludes that in plumbism, the blood becomes loaded with uric acid not from increased formation but from decreased excretion.

*Pyremic variations due to attacks of the paroxysmal neuroses.*—All of the paroxysmal neuroses are recurrent, some periodic, affections; and many can be shown to be capable of dispersing hyperpyremia and reducing pyremia. Asthma and major epilepsy operate to this end mainly through the increase of combustion involved in pathologically exaggerated physical exercise. I can offer no experimental demonstration of increased uric acid excretion as the result of an asthmatic paroxysm, but such increase may, I think, be inferred with but slight chance of error. In one case, however, uric acid in the blood was demonstrated by Garrod's thread test between paroxysms of asthma in a child.[18]

In cases of epilepsy Garrod found uric acid present in the blood.[19] And Haig has shown in a case of major epilepsy that in the hours preceding the fit, the uric acid excretion was very small; that the excretion rose with each set of fits and fell in the intervals; that in the most severe the excretion rose very high; and that when the fits finally ceased, the excretion returned nearly to the normal.[20] He also showed in another case that the amount of post-epileptic excretion was proportionate to the severity of the fit.[21] These observations, which have been in great part confirmed by Herter and Smith,[22] are entirely consitent with the hyperpyremic view of uricemia.

*Migraine* in some cases operates to disperse hyperpyremia and reduce pyremia, through interruption of the carbonaceous income, from anorexia and cessation of digestion and absorption. And Haig finds that while for some days before the attack the excretion of uric acid is low, the excretion during the attack is greatly increased. Other observers have, I understand, since found that during migraine attacks, the excretion of uric acid may be diminished. It seems to me that these two seemingly inconsistent observations are reconcilable on the hyperpyremic view. In health, the daily excretion of uric acid depends upon at least two factors, namely, the disintegration in the tissues of nucleoproteid (endogenous uric acid), and the disintegration of purin substances taken with the food (exogenous uric acid). During the migrainous anorexia, the latter source of uric acid is of course cut off, and the excretion will be determined by the continued disintegration in the tissues of nucleoproteid and by the amount of the previous uric acid retention in the blood. It may be that the previous retention was great; in which case its releasement might more than compensate for the loss of exogenous uric acid; here the excretion during the attack would be in excess. It may be, on the other hand, that the previous retention was slight; in this case its releasement might not compensate for the loss of exogenous uric acid; and here of course the excretion during the attack would be deficient.

It follows from the above views, that the uricemia which precedes, and the releasement of the uricemia which succeeds, the attacks of asthma, major epilepsy and migraine, are mere incidents, and exert absolutely no causative influence therein. The argument in support of this contention will be elaborated elsewhere.

*Dietetic Treatment.*—We have seen that it is possible to disperse hyperpyremia and reduce pyremia by simply restricting the carbonaceous intake; and were space available, a series of observations could be given to show that uricemia may be dispersed by the same means. But this, indeed, is already the opinion of many. For example, W. H. Draper says: "One of the best means of avoiding accumulation of lithic acid in the blood is to diminish the carbohydrate, rather than the azotized, foods."[23]

*Variations in uricemia and uric-acid excretion, depending on the intake of uric acid-forming materials.*—Hitherto notice has been taken of those uric acid variations only which depend upon hyperpyremic and pyremic conditions. But there is at least one other series of variations equally, if not more, important, which tend to obscure the variations just considered.

Burian, Schur, Horbaczewski, and Minskowski have shown that the uricacid-forming material consists, not as was formerly thought, of proteid, which given in excess results merely in an increased excretion of urea, but of the nucleins, purins, and alloxur group, bodies contained in varying quantities in some, but not in all, of the animal nitrogenous food stuffs; such food-stuffs are mainly roe, sweetbread, meat, and the extractives generally. It has also been shown that rather more than half the uric acid excretion of an individual living on an ordinary mixed diet, represents the introduction with the food of these uricacid-forming materials; and that the remainder, mainly, if not wholly, represents the disintegration of the fixed nucleoproteid of the organism. These moieties constitute, respectively, the exogenous and the endogenous uric acid of Chittenden.

Hence, as is well known, an ordinary meal is shortly followed by an increase in the uric acid excretion. This was demonstrated by William Roberts.[24] That the increase depends in the main upon the production of uricacid-forming material, and not upon digestive leucocytosis, as supposed by Horbaczewsky, is shown by the facts, recently demonstrated by Camerer, that the post-prandial increase is not marked unless the food contains nuclein; that on a diet consisting of egg albumin the increas is very slight; and that during the digestion of non-nitrogenous food, the output is actually diminished.[25]

While these observations show undoubtedly that the main factor in the post-prandial increase in uric acid excretion, is the intake of uricacid-forming material, none of them, to my mind, finally preclude an increase of uric acid formation from digestive leucocytosis. The fact that the increased excretion which follows the ingestion of nuclein-free proteid, such as egg albumin, is slight, does not preclude it, for the increase is there. Neither does the fact that the digestion of a purely carbonaceous meal is followed by an actual decrease of uric acid excretion; for a purely carbonaceous meal will tend to increase pyremia (even in spite of the increased combustion

which follows), and thus tend to cause decreased excretion through retention.

*General conclusions as to variations of uricemia and uric acid excretion.*—There seems little doubt, therefore, that uric acid excretion depends directly upon the introduction of uric acid-forming material, and inversely upon the degree of pyremia. There will thus be at least a double column of variations in the excretion of uric acid. But since on a mixed diet, the introduction of uric acid material is for the most part approximately concurrent with the increase of pyremia due to meals, it follows that the resulting opposite variations in uric acid excretion, will overlap and tend to obscure each other.

If it is desired to throw into bold relief the variations due to the one factor, the variations due to the other must be as far as possible eliminated. Haig's main object in treatment is to avoid the introduction with the food of all uric acid-forming material. For this reason, it seems to me, that in Haig's investigations those variations in the excretion of uric acid which depend upon pyremic variations, stand out more prominently than they do in the investigations of many other observers who have worked at this subject.

The argument for the twofold causation of uricemia and uric acid excretion, seems appropriately clinched by the following two pertinent observations:

1. *The delayed excretion of uric acid which in the gouty follows the ingestion of uric acid-forming material.* On the view propounded in these articles, the gouty are frequently more or less hyperpyremic; and Von Noorden points out that the rise of uric acid excretion after the ingestion of purin substances, appears in gouty patients to be much more delayed than in the healthy.[26] Such delayed excretion is clearly explicable by hyperpyremic retention.

2. *The uniformity of uric acid excretion during starvation.* During starvation the carbonaceous income from the alimentary canal necessarily ceases. The carbonaceous income is then derived from the carbonaceous material stored in the tissues. And there is good reason to assume that the income so derived is regulated solely by the demand, not in part by the supply, of fuel, as it is in ordinary circumstances. If so, all pyremic variations will tend to subside, and there will remain, at least for a time, a uniform pyremic level. Thus one source of variation in uric acid excretion would be removed. And it needs no argument to show that during starvation the introduction of uric acid-forming material ceases. Thus the second source of variation in uric acid excretion is removed. Hence we should expect in starvation to find uniformity of uric acid excretion. This expectation is borne out: "Maress has found that every individual excretes after the thirteenth hour of fasting an almost constant amount of uric acid" (Levison[27]).

# REPORT ON THE TUBERCULOSIS CLINIC AT GOUVERNEUR HOSPITAL.*

BY STELLA S. BRADFORD, M.D.,

AND

N. GILBERT SEYMOUR, M.D.

NEW YORK.

CLINICAL ASSISTANTS GOUVERNEUR DISPENSARY.

THE opening of a separate clinic at Gouverneur Hospital for the treatment of tuberculous cases was a further step in the policy, inaugurated there in 1903, of dividing the general medical dispensary into several distinct classes, and of placing these classes under the charge of clinical assistants to the visiting physician. This plan was adopted in order to relieve the house staff of the undue burden of so large a medical class, as well as further to systematize the work in the Out-Patient Department. A skin clinic and a class in the nose and throat had already been formed at the time that we were asked to undertake the work in tuberculosis.

By this separation of the dispensary into special classes, a very considerable number of cases had already been withdrawn from the general medical clinic; but there were, nevertheless, too many patients applying daily for treatment to admit of any very thorough examination in the pulmonary cases. Such examination as was possible at the time, with the unavoidable crowd and noise of a large clinic in limited quarters, was bestowed upon each patient whose history or symptoms indicated some pulmonary affection. A specimen of sputum was sent for examination to the Board of Health. If the examination or sputum were positive, the case was duly reported and received such treatment as was possible under the circumstances.

The majority of patients reported as tuberculous came with varying regularity for a few days—or weeks at most—and then dropped out of view. Those who experienced little relief from the symptoms for which they originally sought treatment soon became discouraged or dissatisfied, and drifted off to other general medical clinics, where they no doubt repeated the same routine, changing from clinic to clinic, until they were finally transferred to a hospital, left town, or, not the least frequent termination to the sequence, died.

On the other hand, those tuberculous patients who improved under treatment invariably did what they still not infrequently do—ceased coming for regular observation until they had a relapse or recrudescence, and returned, finally, in worse condition than at first.

This is the common history of the tuberculous cases in every dispensary, however fortunately situated, where such patients are not treated in a class by

* Read before the Gouverneur Hospital Alumni Society at the Academy of Medicine, June 13, 1905.

themselves and under a system designed for their peculiar needs. These considerations, and others of no less importance—as sanitation and prophylaxis for other patients—have led to the development of a scheme for establishing separate tuberculosis clinics throughout New York, districting the city, as it were, for the care, and especially for the prevention, of tuberculosis. Separate classes of this sort then existed at the Vanderbilt clinic and Polyclinics, while in the new dispensary at Bellevue, not then completed, special rooms were reserved for this purpose. But at the time the Gouverneur tuberculosis clinic was opened, no other city hospital was treating its tuberculous patients in separate classes.

We undertook the work at Gouverneur in October, 1903. There was at first, on an average, one case a day referred to us from the various departments of the dispensary for further examination and for treatment. Our clinic was conducted in what is known as Room 2, of the old dispensary, and still is, in fact, for the new wing of the building, in which we hope to have better quarters, is not yet completed. Our hours, from ten to twelve, three days in the week, were shared in part by the general medical, and at first by the nose and throat class as well. Often as many as twenty patients, men, women, and children, were crowded into the one small room during a part of the time. The confusion in the room itself, combined with the noise of heavy trucks on the cobbled street outside—the dispensary is below the street level, and one gets the full benefit of all sounds without—combined to make an uproar in which examinations of the lungs were often practically impossible. These difficulties, however, were incidental, and have been largely modified by the withdrawal of the nose and throat clinic to an adjacent room, the advancement of our hours to eleven to one, and an improved method of handling our cases, which we developed after the appointment of a clinic nurse.

Such difficulties as we still encounter bid fair to be further obviated in the new dispensary, where we shall have adequate space and quiet, and when the clinic hours shall be changed to afternoon, a plan now under favorable consideration. It should be said in support of this latter change that it will not only bring our hours into conformity with those of the other tuberculosis clinics, but, of far greater importance, it will enable us to secure the afternoon temperatures of our patients.

Our clinic opened, then, with an average of three new cases a week. We began at once to impress upon these patients the necessity of regular attendance at the clinic, regardless of their improvement or the reverse. As a result, we were able to record an average daily attendance during the second month, November, 1903, of seven; during December of ten; and in January, 1904, of fourteen. From that time until January, 1905, the daily average slowly but steadily increased, reaching its highest mark January 6, 1905, of thirty-six cases in the one day, and maintaining an average now of between twenty and thirty daily, *i.e.* sixty to ninety cases treated each week.

Our number of new cases, by day or by week, does not show so regular an increase, varying greatly at different seasons of the year and under varying conditions at the clinic, and in part also, with the more or less active coöperation of the several sources from which we derive our patients. These sources are chiefly the general medical clinic itself, the United Hebrew Charities Society, the Charity Organization Society, other patients, and occasionally other tuberculosis clinics, which refer cases living in the Gouverneur district. For example, during the month of May of this year we have had twenty-four new cases—five from the medical clinic, ten through other patients, four of their own volition, and five from the Hebrew Charities.

Usually a larger proportion of our new cases are sent us, either directly or indirectly, from the United Hebrew Charities, and this leads to a consideration of the class of patients with which we have chiefly to deal. The overwhelming majority are of foreign birth, chiefly Russian, Austrian, or Polish Hebrews. Other nationalities represented are Hungarian, German, Irish, English, American, Norwegian, and Italian. The proportion of men to women is about two to one. To state it statistically, of the 338 patients who have applied for treatment in our clinic from October, 1903, to June, 1905 there have been 200 men, 97 women, and 41 children. As to the nationality of these patients, 145 were born in Russia, 45 in Austro-Hungary, 85 in the United States (though many of these were of foreign parentage), 22 in Ireland, 14 in Germany, 5 in England, 3 in Poland, and 1 each in Norway, Italy, Canada, and Australia.

Their ages vary widely, every decade from the first to the eighth being represented. Most of the active and advanced cases are to be found in the third and fourth decades, that is, between the ages of twenty and forty years, and 44 per cent. of our clinic are of this age.

As to the severity of the cases treated, they vary as widely as the ages. We have had them in nearly every stage from the incipient to the very advanced. For purposes of rough classification we have divided them into four general groups—early or incipient, active, advanced, and quiescent. Of our positive cases, so far, the majority have been incipient or active, and of very few could we declare that the process had become quiescent. Of course, a considerable number of the cases admitted prove, on further examination, non-tuberculous, and these we refer to whatever clinic they may belong. Also, there are a not inconsiderable number of cases of such doubtful character that we keep them under observation many weeks or months before we can arrive at a diagnosis—if we are able to do so at all. These are the cases of indefinite or suggestive history, vague physical signs, and negative sputum. One such case will amply illustrate:

Case No. 87. Female, housewife, aged 43, Russian, admitted May 6, 1904. Mother died of "lung disease." Previous personal history negative. About eight years ago patient began to cough a little and to lose flesh and strength. These symptoms have gradually increased. On admission, patient had slight cought, worse in the morning, when the expectoration was profuse. No severe hemoptyses, but bloody sputum at intervals for years. She complained of pain in the chest and dyspnea on exertion. Her appetite was poor and bowels constipated. She had lost fourteen pounds previous to admission. On the first examination of the chest, expansion was poor and breath sounds feeble. Fremitus slightly increased at left apex. Percussion impaired throughout. No localized areas of dullness. No râles. A later examination practically confirmed the first, but a few sibilant râles were heard on the left side at the end of inspiration. Heart negative. Further examinations were similar. Repeated sputum examinations were negative.

This woman has reported regularly at the clinic for over a year with little improvement. She has repeatedly had bloody sputum and frequent digestive disturbances. Her chief single complaint is pain in the chest and back, which we have failed to entirely relieve. Her cough has diminished, and

her temperature, which was slightly elevated in the morning at first, is now normal. Her weight has fluctuated, varying several pounds above or below that on admission, but the steady loss reported in the history has been checked. The infection, whatever its original nature, seems to have been retarded; but we are unable to determine the extent of the lesion, and we have been unable to wholly relieve the symptoms.

We base our diagnosis upon the combination of history, symptoms, physical examination, and examination of sputum. Of these, naturally the two latter take precedence. They are, however, often insufficient in themselves, or even misleading. Such a case as the one just cited illustrates this. A very large number of our cases give a negative sputum at some period of the disease, if not throughout the time they are under observation. To be exact, of the total 338 patients admitted, 261 have been reported to the Board of Health as cases of pulmonary tuberculosis. Of this 261, only 75 have had positive sputum on first examination. We are unable to state the significance of this large proportion of negative sputum examinations in otherwise positive cases.

In these doubtful cases, we have kept the patients under close observation, treating them symptomatically when necessary, and making repeated examinations of the chest and sputum. Within the past month, however, we have been honored by the appointment of two attending consultants to whom we shall be able hereafter to refer our perplexing cases for expert testimony. These consultants are Dr. S. A. Knopf and Dr. Lewis A. Connor, who will attend the clinic alternately at intervals to give us the benefit of their advice and experience.

In regard to our treatment at the clinic, it is our ideal to "treat the patient rather than the disease," but we must frankly admit that we frequently fail to attain this end. The number of patients at the clinic and the limits of time and space make some sort of routine more or less imperative. Our method is, in outline, as follows:—A complete history is first elicited, so far as possible, from the patient himself, or from his family or friends. In this an interpreter is frequently necessary, as the majority of these patients speak no English at all, or very little, and often their German is such a jargon of Russian and Hebrew, or Yiddish, as to be perfectly unintelligible to us. In taking the history, we use the printed blanks drawn up by Dr. Miller, head of the Bellevue Tuberculosis Clinic, and now in use in all the city hospitals. After the history is taken, the patient is subjected to a thorough physical examination, including chest measurements, height, weight, and temperature, pulse and respiration, for all of which there are special records on the chart. He is then provided with a card for the clinic, and a bottle in which to bring a specimen of sputum for the Board of Health examination. Usually, he is given an initial dose of calomel and salts, which the condition of his digestive tract almost always indicates; and if his cough is severe we begin at once with heroin, prescribing gr. 1-24 in aqueous solution three or four times a day. It has been our experience that the failure to prescribe anything on the first visit, or to neglect the symptoms for which the patient seeks treatment, often results in the subsequent disappearance of the case, his first visit being his last.

It is here that our clinic nurse makes herself invaluable. After we have finished our examination of the patient, supplementing the prescriptions with a few simple instructions in hygiene and the care of the sputum, the nurse secures from him explicit directions for reaching his home—not always the simplest matter in a crowded tenement district—and she calls upon him there in the course of the next forty-eight hours. Her written report, appended to each history, states the character of the premises and rooms, their condition, amount of air space, and sanitation, as well as the number in the family, their financial circumstances, hygiene, and immediate needs. She reinforces our instructions, giving practical directions as to the ventilation, sleeping arrangements, food, and the care necessary to the cure of the patient and the protection of his family. Old patients are revisited at intervals and reports made on their observance or neglect of these instructions. Cases which fail to report regularly are looked up by the nurse and requested to return for treatment, or until discharged by us. If they fail to do so, or repeatedly neglect instructions, they are stricken from our active roll, or are referred to the Board of Health for forcible commitment to some hospital.

During clinic hours, our nurse weighs the patients, takes their temperatures, and distributes prescriptions for the milk and eggs supplied by the hospital to those patients whom she has reported destitute, and whom we select as candidates for the additional nourishment.

Some idea of the work accomplished by Miss McConnell, the nurse assigned to Gouverneur, may be gathered from her report for the months of March, April, and May, 1905:

| | |
|---|---|
| Number of cases under observation at clinic, March 1 to June 1 | 76 |
| Number of new cases during months of March, April, and May | 47 |
| Total number of patients treated | 123 |
| Total number of visits to clinic by all patients | 261 |
| Number of cases untraced | 4 |
| Cases not reporting regularly at clinic | 24 |
| Cases sent to hospitals | 6 |
| Cases sent to the country or their homes in Europe | 6 |
| Cases who have died | 1 |
| Total number of cases discharged | 38 |
| Total number of cases under observation June 1 | 85 |
| Number of primary visits at the homes of patients | 22 |
| Number of secondary visits at the homes of patients | 157 |
| Total number of visits at homes | 179 |

Extra diet relief was provided for thirty patients during these months. It was obtained from the following sources: From Gouverneur Hospital, 916 quarts of milk and 168 dozen eggs; from the New York Diet Kitchen, 336 quarts of milk; from the United Hebrew Charities, 20 quarts of milk.

To return to our routine treatment. The new patient is instructed to report on the next clinic day with his specimen of sputum. At his second visit he is usually encouraged by a relief, to some extent, of his symptoms. If he is certainly tuberculous, he is told the nature of his disease, the probability of improvement if not of cure, and the necessity of patience during a long course of treatment. The importance of a strict observance of the instructions given him and of a regular attendance at the clinic is also impressed upon the patient. He is then given more detailed instructions about diet, exercise, fresh air, and bathing. If his case is suitable, he is taught the simple breathing exercises recommended by Dr. Knopf, and used by him at the Riverside Sanatorium and at the Board of Health clinic.

The instruction thus begun is continued during the weeks following, and is reiterated by us and by the nurse during the entire time the patient is under our care. Our chief difficulties here lie in three things: First, in the language; second, the intelligence of the patients; and third, their environment. It is difficult to explain to these people the nature of their disease, the importance of the long, regular course of treatment, and the value of hygiene rather than medication. Not alone does the language make it difficult, but the intelligence of many of these patients seems to be inadequate to any appreciation of the matter. Again, even though they understand us and are intelligent enough to grasp the situation, many of them are unable to get good food, abundant water, or even fresh air. One of the most discouraging factors in the situation is the environment in which our patients live. These people must work to live and to support their families. If we send the parents to hospitals, the children must become dependent upon charity or a burden for some equally poor relative. If we allow the parents to work, the majority, being tailors and housewives, are confined all day in crowded, ill-ventilated rooms. If those who work in shops protest against these conditions, they are apt to be suspected of consumption and to lose their jobs. Such an experience was reported to us recently by one of our patients who is a tailor, and who was discharged from his shop because he asked to have the windows opened.

The occupations of other patients, such as bakers, cooks, waiters, and barbers, make them a positive menace to the community. Few, indeed, are engaged in occupations which may be considered suitable, *e.g.* peddlers, drivers, messengers, and the like. That this matter of occupation is of vital importance in the treatment may be illustrated by one case.

Case No. 21. Male, 15 years old, born in United States. Admitted to clinic December 16, 1903. His mother and three brothers cough. The mother was recently admitted to the clinic as a patient. Patient's previous history is negative, except that he has always been subject to "colds." His habits are good. About six months ago he began to work as a printer, and about the same time he developed a cough with bloody sputum. For the three months previous to admission he had been coughing more, raising more blood, and losing flesh. On admission he had a good appetite, bowels regular, no fever nor night sweats, but he was pale and ill-nourished. Physical examination showed roughened breath sounds and occasional sub-crepitant râles at right apex. Heart overacting but not enlarged. Otherwise negative, further examinations confirmed the first, and although the sputum, on repeated examination, was negative, we reported the case as one of early pulmonary tuberculosis.

We put the boy on cod liver oil, gave him breathing exercises, and advised him to give up his indoor work and secure some employment which would keep him out of doors. This he was unable to do at the time, and during the first three months of treatment he showed little improvement in symptoms and no gain in weight. The loss of weight, however, seemed to be checked. At the end of three months, the patient succeeded in securing work as a messenger boy, and was distinctly better for a time, all symptoms abating; but he soon returned to his former job, which gave him better pay, and within a week or two there was a return of the cough and bloody sputum, with the addition of afternoon rise of temperature and night sweats. His appetite was poor and bowels constipated. We put him on nux vomica, cod liver oil, and heroin, and renewed our efforts to change his occupation. In March, 1904, he stopped work altogether for a time, and began at once to improve again in all respects, gaining ten pounds in the following two months. Then he resumed work, at first as a messenger boy, and later as a shipping clerk, an employment which has kept him out of doors six hours daily. Under this change, his symptoms entirely disappeared and we were able to stop all medication. The patient was only required to report occasionally at the clinic for observation. At present, one year after his change of occupation, he weighs 122 pounds, as compared with 95½ pounds on admission, and, except for a tendency to catch cold or to tire easily, he is without constitutional symptoms.

To realize an ideal, we should be able to give suitable employment to those able to work, *i.e.* light out-of-door labor, preferably in the country, and to send to suitable hospitals all those too ill to work, and unable to receive proper care in their homes.

The Committee for the Prevention of Tuberculosis, working in cooperation with the Charity Organization Society, has recently elaborated a scheme by which tuberculous patients who are able to work can be established, with their families, as tenant farmers in country districts near New York. So far, none of the cases which we thought suitable for such a position has had the courage or the intelligence to make the attempt. We have sent patients to all the available hospitals, from Raybrook to the Metropolitan, and our chief difficulty is in the long waiting lists due to inadequate accommodations. Heretofore there has been no provision for an intermediate step from hospital patient to a position of physical and financial independence in the accustomed home. Such a step is provided to some extent by this opportunity for farm life; but an institutional farm, in some respects similar to the George Junior Republic, would prevent many more cases "apparently cured" in hospitals, from slipping back into their old lives, as they now do, and give them the strength and ability to secure permanent independence.

Our further treatment of the cases is largely symptomatic. We use heroin in a considerable number, beginning with a twenty-fourth of a grain three or four times a day, and increasing or diminishing the dose or interval according to the indications. We have given as much as a twelfth every three hours for a considerable time without any ill effects. On the other hand, we have been able to decrease the dose in many patients after the abatement of the cough, until they take but one dose in the twenty-four hours, or are able to get along without any. Heroin has given better results in our experience than any of the several other drugs we have tried, and, with the exception of occasional digestive disturbances or constipation, which may have been due to its continued administration, we have observed no contraindication to its use. Of course, a certain number of cases are not relieved of their cough by anything we have been able to prescribe, but even in these cases heroin seems to act at least as well as, if not better than, other preparations.

We have used both cod liver oil and ichthyol internally in a considerable number of cases, with about equally good results, and all of our patients are ordered milk and eggs in such quantities as they can afford, or we supply. This additional feeding has resulted in gains in weight to thirty-five patients, varying from one pound in twelve months to twenty-eight pounds in eighteen months. In spite of treatment, thirty-five have lost weight, the least being two pounds in eighteen months, the most seven pounds in three months. The remainder have maintained a certain average weight throughout treat-

ment, varying a few pounds either way at different times. In speaking of gains or losses in weight, it should be borne in mind that nearly all of these patients report more or less loss of weight on admission. Of 115 patients who were able to state their average weight in health, only three showed no loss of weight at all. The remaining 112 gave a history of loss varying from five pounds in five years to thirty-eight pounds in two weeks. The average loss before admission was nineteen pounds in fifteen months. So, if we are unable to report phenomenal gains under treatment, we may at least congratulate ourselves in the majority of cases upon checking the most obvious effect of the disease.

Our results in other respects may be briefly stated. Of the 338 cases which have been admitted during the sixteen months of the clinic, 85 are still under observation; 120 have disappeared, leaving no addresses whereby we might trace them; 52 have gone to hospitals, the country, or to their homes in Europe; 14 have been referred to other clinics as non-tuberculous; and 9 have died. Fifty-one cases have been discharged because they refused to return regularly for treatment, repeatedly neglected to observe instructions, or were being treated elsewhere. Seven cases have been discharged as "apparently cured," though they are still requested to report occasionally for observation. In using the term "apparently cured," we are following the classification recently approved by the Tuberculosis Congress. Such cases, to quote the report of the committee, are those in which "all constitutional symptoms and expectoration with bacilli have been absent for a period of *three months;* the physical signs are those of a healed lesion."

These results are not startling in any way, but we may venture to believe that the clinic has accomplished four definite and excellent results: (1) It has withdrawn the tuberculous cases into a class by themselves, thus relieving the overcrowded medical clinic and providing some protection to non-tuberculous patients. (2) It has provided a place for the systematic treatment of ambulant cases of the disease in a district of the city thickly populated and extensively exposed to the contagion. (3) It reaches cases heretofore untreated, or treated irregularly and unsystematically at a number of general dispensaries, and the results of this systematic treatment of these cases show a decided relief to most of the more obvious and distressing symptoms of the disease; a prolonged life, actually and economically, to many, and the apparent cure of a few. (4) The patients so treated have become a source of education in their homes rather than a menace to their associates.

To summarize the report in conclusion, the clinic originated in the natural progress of events, as a part, on the one hand, of the subdivision of the Gouverneur Medical Dispensary into classes, and, on the other, as a part of the system of clinics organized all over the city for the uniform treatment of tuberculosis. Our original difficulties bid fair to be largely obviated in the new dispensary, and with the change to afternoon hours. The assignment of a visiting nurse has added immensely to the value and success of the work. The distribution of milk and eggs to suitable cases is an important factor in the treatment.

Finally, our results show a steady increase in the number of tuberculous patients treated; an average improvement among these patients, both as regards their condition and in their observance of sanitary regulations; and a distinct benefit to that community in which Gouverneur Hospital belongs.

## CYSTOSCOPY AND URETERAL CATHETERIZATION IN GYNECOLOGY.*

By HENRY DAWSON FURNISS, M.D.,

NEW YORK.

INSTRUCTOR IN GYNECOLOGY, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

In the practice of gynecology one is impressed with the number of patients encountered suffering from symptoms referable to the uropoetic system. While bladder diseases are not so frequent in the female as in the male, they are plentiful enough. It seems that one reason for their more frequent occurrence in the male is due to the fact that in men the urinary stream is liable to be impeded by enlarged prostate, stricture, etc., while in the female an obstruction to the urinary outflow is infrequent. It is a well-known fact, demonstrated experimentally and clinically, that the simple introduction of organisms into the bladder is not sufficient to produce a cystitis; to this must be added a predisposing cause, as congestion, obstruction to the outflow of urine, or traumatism, as from an instrument or a stone. In the female the shortness of the urethra and its position render it liable to infection; besides this, the bladder is liable to infection from the extension of disease processes of the neighboring structures more often in women than in men. The liability to extension of inflammation from the bladder up the urethra is greater in men than in women, owing to the fact that retention, with back pressure, is more frequent in the male sex. The kidney affections may be primary (infection taking place through the blood), secondary to disease of other tissues far or near, by deposit or continuity, or due to an ascending infection.

When a woman comes to you suffering from any urinary disturbance, it is important that a most careful history be taken, for some point that may seem trivial to her may give the clue to the whole situation. In the case of stone in the kidney, for example, hematuria with a slight pyuria may be the only symptom present, because the stone so closely fits the surrounding structures that it is unable to move and cause pain; yet careful questioning may elicit the fact that years ago this patient did suffer from pain in the kidney region. In others, the family history, or the history of the patient's previous health, may serve to direct your attention in the proper way. Recently I had a case in which a suggestive point was misleading. The woman was thin, and of the type often spoken of as tuberculous. When a child, she had arthritis of the right knee, with subsequent ankylosis. This immediately brought into my mind, taken in conjunction with the other symptoms, which agreed, tuberculous cystitis; this was an error, as proved by the cystoscopic examination and the subsequent history.

A careful pelvic examination will bring out or negative diseases of the neighboring organs. In many instances a bimanual examination will enable us to mark out an area of disease in the bladder, the urethra, or the ureters, which may be thickened and tender. The kidneys can often be palpated, thus indicating something of their location, size, consistency and form. The urine should be examined chemically, microscopically, and bacteriologically, especially when tuberculosis is suspected. The urine shows the signs, or effects, of disease. Sometimes from an examination of the urine we are enabled to determine the source of the blood or the pus present, but in most instances not. The finding of atypical cells, or the examination of pieces of growth

*Read before The Medical Association of the State of Alabama at the annual meeting in Montgomery, April 18, 1905.

passed in the urine will determine the presence and nature of a neoplasm. By a careful history, a thorough physical examination, and a painstaking urinalysis, we may be able to make a diagnosis of the nature of the disease and its location, but very often not; and it is just here that cystoscopy, meatoscopy of the ureteral orifices, and ureteral catheterization furnish their most valuable aid.

A few words in reference to the method of examination and the instruments to be used. No one instrument and no one method are going to be found entirely satisfactory. Personally, I prefer an instrument of the water dilating variety, direct view with catheterizing attachment, as embodied in the Tilden Brown cystoscope, for with this we can examine all of the bladder except the anterior wall, which is seldom affected, and catheterization of the ureters with a direct view instrument is far easier than with an instrument of the prism type. Nearly all examinations with the water dilating instruments can be carried out without anesthesia, and with very little discomfort. In the Kelly instrument we have one that is suitable for those cases in which we cannot get a clear medium for examination on account of the clouding of the water by the rapid collection of pus or blood. It is necessary to use this form of instrument in those cases in which the bladder is so small and so contracted that sufficient distention is not to be had for the water dilating type of instrument. In this method the dorsal position, with the hips elevated, the Sims, or the knee chest position is necessary to secure the requisite amount of bladder distention for a satisfactory examination. The stouter the patient, the more difficult the examination. The method is painful, often requiring anesthesia, and it is annoying to constantly have to remove the urine that accumulates in the bladder during an examination, but this is not so troublesome in the knee chest position. The newer Kelly cystoscope carries a small electric light at the bladder end of the instrument, while the Cullen modification carries it on a beak. The instruments which depend on air dilatation by introduction of the air under pressure with a hand syringe secure dilatation, but examination with them is attended with more pain than with an instrument that secures the requisite amount of dilatation through atmospheric pressure. In the Tilden Brown, we have one that we can use as a direct view examining and catheterizing instrument, in which we can substitute a prism set of lenses if necessary, and one which is a Cullen when the telescope is removed, thus making it suitable for examination of the bladder under atmospheric pressure, or for making topical applications to the bladder wall.

While the cystoscope is an instrument of the utmost importance from a diagnostic and therapeutic standpoint, it must not be forgotten that danger sometimes attends its use, and that it has a mortality, though small. If from the symptoms, and the finding of tubercle bacilli in the urine, the diagnosis of tuberculous cystitis is made, the examination as a routine procedure should not be done, as nearly all of these cases are much aggravated by any intravesical applications, especially the use of the cystoscope. I had one unpleasant experience with such a case, and for a while the outlook was grave. In these cases, if the urine is sufficiently clear when an examination is made, it is advisable to use the urine in the patient's bladder as the medium through which the dilatation is to be secured.

Unless contraindicated, and when carefully performed in a gentle and aseptic manner, the method is relatively free from danger. In discussing a subject as large as this, "Cystoscopy and Ureteral Catheterization in Gynecology," it is manifestly impossible to indulge in any detail, and it will be my effort mainly to interest you by showing that many diagnoses that were only probable before the introduction of the cystoscope may now be made absolute, and at the same time to speak of some of its therapeutic uses.

For the detection of foreign bodies in the bladder, we have a method that is certain, that is often less painful than sounding, and one that gives the knowledge not only of the presence of a foreign body, but also of its shape, size, and consistency, thus offering the suggestion as to the best method of removal, and many times, the means. Many stones are overlooked in examining with the searcher, for unless the bladder is well dilated they may become hidden between the folds of the mucous membrane, and in a dilated bladder a small stone may be propelled in front of the examining instrument and elude any contact with it. In the case of such foreign bodies, as a piece of a rubber catheter, even should the sound strike it, no click would be elicited.

A fact that impresses one even at the beginning of cystoscopic work in gynecology is the amount of urinary disturbance than can exist with so little structural change. Many of the cases of cystitis in which the frequency and the urgency of urination are marked, will show only a slight hyperemia around the neck of the bladder to account for the symptoms. Some authorities consider these cases instances of slight infection, and have named the condition trigonitis. A fallacy, the idea that all cases of cystitis are general, is cleared up by cystoscopic examination. While many cases are general, a large number are more or less local, sometimes spoken of as patchy. In those cases of cystitis, not due to causes from without, that have resisted the ordinary methods of treatment, the topical application of drugs through the cystoscope immediately to the affected area is often attended with most pleasing results. With the aid of the cystoscope, this treatment is not, as a rule, difficult; we are able thus to determine whether the condition is improving, and do not have to depend on the patient's statements, which, while made in good faith, are often erroneous.

In young nulliparous women suffering from cystitis, if the gonorrheal element can be eliminated, tuberculosis of the bladder should be considered. In some cases of tuberculous cystitis, when seen early, we are able from the appearances as seen through the cystoscope to determine whether the condition is primary in this organ, or secondary to tuberculosis of other portions of the genitourinary apparatus. Contrary to what is the general impression, tuberculosis of the bladder, except in those cases of general miliary tuberculosis, does not begin as tubercles, which later break down, but the first lesion noticed is an infiltrated area, generally on the posterior wall back of the trigonum, which is dark red, somewhat swollen, and in which no blood vessels are to be seen. In tuberculosis of the bladder, due to a descending renal affection, the lesion is usually situated around the ureteric orifice of the kidney which is affected. One of the characteristics of tubercular lesions is that the mucous membrane between is apparently normal. The determination as to whether the condition is primary or secondary in the bladder is of the utmost importance in deciding on the treatment to be employed. From symptoms and urinary examination alone, it is most difficult, and often impossible, to name the source of pus or blood in the urine, especially where hematuria or pyuria are the only symptoms. It is in these cases that a diagnosis is most important, for the treatment of the causative factor is often surgical, though not

necessarily so. It would be sorry surgery to make a series of exploratory operations on a tract so extensive as the urinary system, when by a simple cystoscopic examination, and sometimes ureteral catheterization, the source of the pus or blood is made apparent. A symptomless hematuria may be due to the rupture of vesical veins, neoplasm of the bladder, or conditions in the kidney or its pelvis, such as chronic granular nephritis (Fenwick), the breaking down of the crude tubercle, or angioma of the renal papilla, a rare condition. How illogical to attempt to treat a hemorrhage without localizing symptoms, when the sources of such are so numerous, and distributed over such a great field, when a simple cystoscopy will show us the origin of the hemorrhage, and in those instances in which it is due to a bladder lesion, the cause. When the blood is seen to come from either ureter, the history, with a careful urinalysis must be considered in determining the etiological factor. As an illustration of this, the patient brought me by Dr. W. G. Vincent will serve to show the importance of cystoscopy and ureteral catheterization.

This patient was thirty-seven years old, with a negative family and previous history. Two months ago he began to notice that the urine was dark colored, and, as it became progressively worse, he consulted Dr. Vincent, who found a large amount of blood in the urine. There were no symptoms to locate the origin of the hemorrhage, and the only trouble to the patient besides the hematuria was the nervousness it caused, and a slight loss in weight. Dr. Vincent brought the patient to me on April 12 for cystoscopy and ureteral catheterization. As nothing in the bladder to account for the hemorrhage was found, the ureters were catheterized, and bloody urine drawn from the right side, while the urine on the left was clear. On April 17, Dr. Vincent cut down upon the right kidney; it was a large (five and one-half inches long), mottled kidney, with no evidences of stone, growth, abscess, or tubercle. The kidney was decapsulated, and a small section removed for microscopical diagnosis. Dr. Brooks, pathologist for the New York Post-Graduate Hospital, declared this tissue to be that of "the large red, or mottled, or chronic hemorrhagic, or Wiegert's kidney." (August 15. After the operation, the amount of blood in the urine became progressively less, and when the urine was examined recently none was to be detected even with the microscope.) Dr. Vincent will shortly report this case in detail in one of the leading periodicals.

When pus or blood is not from the urethra or the bladder, it is to be inferred that it is from the ureter, the pelvis of the kidney, or the kidney itself. Unless the amount is small, this can be seen coming from the ureter of the affected side, and does not necessitate catheterization of the ureters, but in case the amount of pus or blood is not sufficient to be demonstrated macroscopically in the ureteral effluxes, the ureters can be easily catheterized. Pus or blood can come from both the bladder and the kidney at the same time. Not long since, Dr. W. E. Swann brought me a patient, a woman, forty years old, who for seven years had had a growth on the upper left side of the urethra, which during the past few months had rendered micturition difficult. A mild cystitis had developed, the predisposing cause being the obstruction to the urethra, and in addition to this a pyelitis on both sides, the symptoms leading to the catheterization of the ureters being the pain in the kidney region.

While the subject of ureteral meatoscopy or inspection of the ureteral orifices is a very large one, and cannot be more than touched upon in a paper of this length, the axioms of Fenwick will be quoted to give some idea of its importance: ,

1. If a cystoscopist finds an irregular-shaped, caked, and patulous ureteric orifice, he may diagnose destructive changes in the kidney of that side.

2. If no renal tumor can be felt on that side, and he notices that the ureteric orifice is caked, patulous and displaced, he may proceed a step further and diagnose, without hesitation, a retracted inflamed adherent kidney, with probably one or more small cortical abscesses in the upper end of the organ.

3. If, in addition to the caked and patulous ureteric opening, tubercle bacilli are found in the urine, destructive tuberculous changes of the pelvis of the corresponding kidney may be diagnosed, and the kidney nephrectomized—provided that the opposite ureter appears healthy—and the urine obtained from it by catheterizing its ureter appears abundant and of good specific gravity.

4. He may suspect the renal origin of urinary tuberculosis if he finds with this caked, patulous, and displaced ureteric orifice, that extravasations are strictly localized to the ureteric area.

5. But if the disease is far advanced in the bladder, and much of the mucous membrane is stripped away, he cannot, on cystoscopic grounds, assert that the disease originally commenced in the kidney, although the ureteric orifice is caked, patulous, displaced, for these changes are also induced by extension from below upwards. All that can now be asserted under these circumstances is that the kidney is undergoing destructive tuberculous change.

And further: Sometimes we may infer from a markedly vascular ureteric orifice that the pelvis of the kidney on that side is also very vascular; that an elongated turgid ureteric orifice, like a long congested meatus of the penile urethra, denotes dilatation of the responding renal pelvis, and marks a tendency for the ureter to dilate from above downwards. One of the first signs of dilatation of the ureter from below upwards is an oval arched uretric orifice, while the ureter that appears like a golf hole in the cystoscopic picture also denotes dilatation of the ureter, but does not indicate the direction from which this started. Small, puckered, distorted orifices denote preexisting erosive ureteritis. Edema of the ureteric orifice denotes stone arrested in the terminal portion of the ureter, or acute descending renal tuberculosis. Conical protrusion of the orifice, as a whole, usually denotes renal stone, which is causing colics.

By ureteric meatoscopy, we are able to determine the number of ureters entering into the bladder, their position, and whether or not they are functionating.

The ureteral catheter serves many purposes. It may be used as a guide to the ureter in operations where this is liable to be abnormally placed, and should injury occur, the damage can be repaired on it as a splint. The first autopsy that I ever did was for occlusion of the ureters in the suturing of the broad ligament following supravaginal hysterectomy for fibromyoma of the uterus. Had the ureteral catheters been used as a guide in this case, the accident would not have occurred, and had they been passed after the operation, it would have been seen that the condition was one of retention instead of suppression of urine. It is possible that this obstruction might have been overcome by gentle pressure of the catheters, as the broad ligament was sutured over continuously with plain catgut. In another hysterectomy for a large fibroid of the uterus, I saw the ureter injured, but in this instance the ureters had previously been catheterized, so the damage was recognized at once, and the opening in the ureter closed and the peritoneum sutured over it. The catheter was left in place for two days, when it was

removed. The recovery of the patient was uneventful. In carcinoma, the ureteral catheter serves well to mark the ureter in close dissection. Obstructions occur in the ureter, due to pressure of neighboring structures, as well as to disease of the ureter itself; a true stricture sometimes exists, analogous to stricture of the male urethra. The ureteral catheter serves to detect such, this being demonstrated by the obstruction offered to the passage of the catheter, and to the sudden passage of an abnormally large amount of urine immediately the constricted portion is passed. By using tapering catheters, of increasingly larger caliber, the ureter can often be so dilated that retention of urine, with dilatation of the ureter, the pelvis, and even destruction of the kidney tissue from pressure, can be prevented. If a stone is the cause of the obstruction, we may get an impression of it by tipping the catheter with wax; this is also possible when the stone is in the pelvis of the kidney. Tilden Brown, in doubtful cases of radiographs, where it is not certain if the object giving the shadow is in the ureter, passes a catheter armed with a wire stylet to a point in the ureter close to the stone, or above it; then, when a second radiograph is taken, the relation of the suspected stone and the ureter is apparent.

Before the removal of one kidney for any cause, it is desirable to know the efficiency of the other, and this can be learned by collecting the urines from each kidney, and examining them separately (Cryoscopy).

According to Howard Kelly, there are many cases of mild hydronephrosis which are not recognized, and in his hands repeated catheterization of the pelvis of the kidney has given good results. In pyelitis, and especially those cases which have resisted medical treatment, we have an efficient and logical treatment in the irrigation of the pelvis of the kidney with antiseptic solutions. In recognizing and treating pyelitis, when it is a simple pyelitis, we will cure the condition, and prevent its further progress into a pyelonephritis. Good results have been claimed in the treatment of Bright's disease by irrigation of the pelvis of the kidney, but I am inclined to think that the cases that have been benefited are ones of pyelitis with a few casts in the urine, rather than cases of true nephritis.

If I have succeeded in interesting you in this line of work, and in showing you some of the numerous advantages and many necessities of such, I shall feel that the purpose of this paper has been well accomplished.

122 West Forty-ninth Street.

## THE ABUSE OF BROMIDES IN EPILEPSY.

By WM. P. SPRATLING, M.D.,

SONYEA, N. Y.

MEDICAL SUPERINTENDENT OF THE CRAIG COLONY FOR EPILEPTICS; PRESIDENT OF THE NATIONAL ASSOCIATION FOR THE STUDY OF EPILEPSY; MEMBER OF THE AMERICAN NEUROLOGICAL ASSOCIATION, &c.

Years ago I became convinced that the bromides as generally administered did vastly more harm in the treatment of epilepsy than they did good, and the ten years' experience I have had at Sonyea in the treatment of nearly two thousand cases has strengthened that conviction. I do not hold that the bromides always do harm, or that they fail sometimes to do good in the treatment of epilepsy. I think they have a limited range of usefulness in the power they possess of *suppressing* epileptic convulsions.

But I can say this without reservation: *I have yet to see the first case of epilepsy cured by the bromides alone.* Personally I have never given the bromide of potassium to an epileptic. In certain of the epilepsies in women in which the attacks group themselves about the menstrual epoch, I have used some of the other salts with good results, but even then the case must be carefully selected.

When visiting the Bielefeld Colony in Germany years ago, I learned that the bromides were constantly being less employed. At the Craig Colony the average dose of the drug now is fifteen grains a day, five grains to a dose. Some patients get more than this, while many get none.

A short time ago the amount of the drug that was being used was reduced nearly one-half. The result was a considerable temporary increase in the number of attacks, but in a little while the attacks fell to their former number, most of the patients showing mental and physical improvement while free from bromism. To stop the bromides in a chronic epileptic—if it be cautiously done—is sometimes more valuable than to keep him saturated with them to the point of toleration. There is no better proof of the failure of the bromides to cure epilepsy than to stop them after years of use and watch the attacks double or treble in number.

Sudden withdrawal of the bromides without an effective substitute is never advisable. Some epileptics will stand it, but others will be sure to succumb to serial attacks, or to the graver condition of "status epilepticus" which so frequently terminates in death. Most, probably all, patent nostrums recognize the power the bromides have of effecting false and superficial "cures" in epilepsy—cures that terminate with the withdrawal of the nostrum. During the past nine years I have personally analyzed twenty-seven such nostrums and I found the basis of them all, without exception, was the bromide of potassium.

In the hands of laymen these nostrums do infinite harm. In contradistinction to the one point of value bromide possesses in the treatment of epilepsy—that of lessening cortical irritability—there are numerous results from its unscientific use that sometimes make it a positive menace to the recovery of the patient. I am convinced that recoveries occasionally occur in epilepsy, not because of the use of the drug, but in spite of it.

The most remarkable recovery from epilepsy I have known was in a man who had suffered from the disease eighteen years, who had in all 50,000 to 60,000 seizures, who was given for years 120 to 140 grains of bromide with no effect but a steady depreciation in his physical condition, and who began to make a complete recovery after entering the Colony where the amount of the drug was reduced month by month until at the end of the eighth month he was getting fifteen grains a day only. In this case an effort was made to correct deep seated errors in metabolism by giving a drug that only augmented the primary fault. This single instance is worth little more than to show that epilepsy is not always relieved by bromide alone. But the point is: there are thousands of other cases like it.

The chief difficulty in giving the bromides lies in our inability to prescribe the precise individual dose the patient's condition demands. We have paid too much attention in the past to the number of grains administered, and too little to results attained. Notwithstanding its comparative harmlessness, the drug should be used in epilepsy with the same scrupulous care that we use aconite in fever or digitalis in heart disease if we expect to make our patients feel its value, and miss its faults.

In no case let us forget there is a point of physiological toleration—of therapeutic usefulness, beyond which we should not go. Barring exceptional cases, it is never necessary to push it to the point of inducing bromic acne, while to cause bromic dementia with

it, is a blunder inexcusable. For some years after its opening the number of patients admitted to the Craig Colony with bromic dementia was greater than now.

Blunting of the intellectual faculties is a notable result of the bromides, and is first shown in loss of memory. I formerly thought this condition was due to the seizures, but witnessing the complete restoration of memory in so many cases after the bromides had for some time been withdrawn, there was no alternative but to ascribe it to the use of the drug.

Since the origin of the Colony treatment of epilepsy the bromides have, to a certain extent, declined in favor. This decline was a logical result of the recognition of the necessity for the treatment of the individual *in toto,* instead of aiming at the suppression of a symptom only.

We have only to consider the physiological effects of the bromides to understand why they are of so little use in epilepsy. On the respiration ordinary doses produce but little effect; in larger doses they act as depressants. On the alimentary canal they often act disastrously—irritating the mucous membrane and interferring with the reflex activity of the stomach in a way to check the normal secretion of gastric juice, which impairs digestion. They cause constipation, heavy coating of the tongue, and foul breath, a bad taste and a pasty feeling in the mouth, loss of appetite and not infrequently nausea and diarrhea.

On nutrition they act unfavorably in some cases by lessening metabolic changes through depressing the nervous system. They produce unsteady gait; myasthenia, particularly noticeable in the legs; depression and often loss of sexual vigor; forgetfulness and slight degrees of aphasia, usually shown in the misuse of words and the wrong formation of sentences.

On the temperature ordinary doses have no effect; in larger doses they lower the heat of the body by depressing the heart's action and possibly by contracting the arteries, a fact apparently established through the experiments of Brown-Sequard, Mairet, and Amory.*

Some therapeutists assert that the bromides decrease tissue waste. I do not share this belief, but I am convinced that the opposite is oftener the case. Epileptics are notoriously great eaters, and any simple increase in weight in them is not to be ascribed to the bromides, but to their food habits.

Anemic, emaciated, and feeble epileptics who have been taking large routine doses of bromides for years before entering the Colony and who suffer its partial or complete withdrawal after they begin Colony life, show an increase in weight and a gratifying general improvement difficult to believe.

It is an extraordinary fact that since the introduction of the bromides in the treatment of epilepsy by Laycock, fifty-seven years ago, the prognosis of the disease (barring certain well regulated forms of treatment) is no better now than it was then.

After a few years of abandonment of the bromides with the employment of other harmless depressants in their stead, and a general recognition of the principle of first treating the individual instead of a symptom of his disease, we should soon attain a truer estimate of the very limited value of the bromides in epilepsy than we have to-day.

---

**Hyperpyrexia.**—John Britton reports a case in which the patient's temperature on two occasions reached 110.2° and 112.3°. The writer regards the case as one of acute influenza in a neurotic subject. All of the thermometers used, four, registered the same temperature. The patient made a good recovery without suffering any apparently injurious effects.—*British Medical Journal.*

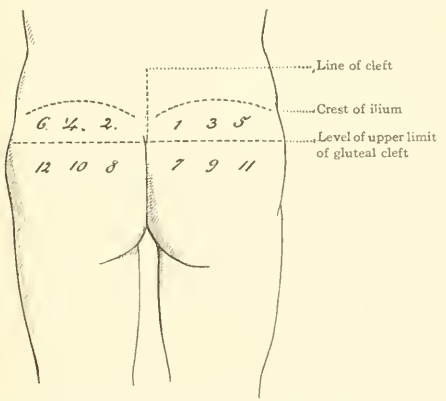
## CONVENIENT POINTS FOR INTRAMUSCULAR INJECTIONS IN THE TREATMENT OF SYPHILIS.

By VICTOR COX PEDERSEN, A.M., M.D.

NEW YORK.

GENITOURINARY SURGEON TO THE OUT-PATIENT DEPARTMENT OF THE NEW YORK AND OF THE HUDSON STREET HOSPITALS.

THE progress which has recently been made in the treatment of syphilis by injections, has been most satisfactory and indicates this method to be the choice in severe cases. The chief objection which has always been urged against the injection method, however, has been the secondary occurrence of subcutaneous or intramuscular nodes and infiltrations. After a little experience, the writer was impressed with the fact that possibly these defects arise only because the injections are repeated at the same point, at intervals too brief and spaces too close to allow full absorption of the drug injected. Salicylate of mercury is probably most commonly employed at the present time, and is the preparation preferred by the writer. His method of using this drug and therein correcting occurrence of nodes is as follows: The gluteal region is regularly employed. It is divided into four quadrants



Quadrants shown, as formed by the vertical line of the cleft and the horizontal line of the apex of the cleft. The numerals 1 to 12 inclusive show the points of injection which are two inches (*i. e.* a needle-length) apart in the vertical and horizontal directions.

by the vertical line of the intergluteal cleft and by the horizontal line passing through the upper limit of the cleft. The injections are given once a week, three in the upper part of each quadrant in the following order, alternating from week to week between the right and left sides: Right upper quadrant, 1 inch from the middle line; left upper quadrant, 1 inch from the middle line; right upper quadrant, 3 inches from the middle line; left upper quadrant, 3 inches from the middle line; right upper quadrant, 5 inches from the middle line; left upper quadrant, 5 inches from the middle line; lower right quadrant, 1 inch from the middle line; lower left quadrant, 1 inch from the middle line; lower right quadrant, 3 inches from the middle line; lower left quadrant, 3 inches from the middle line; lower right quadrant, 5 inches from the middle line; lower left quadrant, 5 inches from the middle line. The illustration indicates this arrangement distinctly. The injections are then repeated, beginning at the same point as the first. Thus it will be seen that thirteen weeks intervene between any two injections at the same point. Thus all tendency toward the promotion of nodes is obviated and full opportunity is given for complete absorption of the drug. The

writer has made several hundred injections in this manner and has never had any tendency toward infection or the production of painful lumps and nodes which persisted more than about two days after the injection, and even these have been rather rare. A large caliber needle, 2½ inches under the head is advised, which has been boiled fully five minutes before being used. Sterilized emulsion of the salicylate of mercury, 1 grain, in 10 minims of benzoinol is employed. The skin is sterilized by scrubbing with tincture of green soap, then with alcohol, and painting freely with iodine. When the skin is deeply stained by the iodine the injection is made. Massage of the point of injection is then carried out for two or three minutes vigorously with sterilized gauze. The mouth of the hole is again painted with iodine and flexible collodion is used as a seal. No other dressing is made. In this way thus far no difficulties whatever have been encountered and the patients greatly prefer the injection to any other method of treatment.

## A CASE OF ACUTE HEMORRHAGIC PANCREATITIS.

By CHARLES M. TINNEY, M.D.,

CHARLESTON, WASH.

The comparative rarity of this disease seems a sufficient excuse for the report of every case in order that we may obtain more definite knowledge for differential diagnosis and perhaps treatment.

The patient, a man 41 years of age, robust and apparently in good health, was first seen by me on April 23, 1905. At this time he complained of distressing pain in the epigastrium, severe frontal headache, eructations, loss of appetite and constipation for three days. The tongue was thickly coated, pulse 96, temperature 99.4°. He stated that he had had general malaise for several days prior to returning from a convention, three days before he went to bed, with gradually increasing discomfort. His habits were unusually good and past history negative, except for chronic constipation, and attacks similar to the present one, but not so severe. They were considered to be due to biliousness. Physical examination was negative except for slight abdominal tympanites. There was no tenderness on deep pressure. A provisional diagnosis was made of an acute exacerbation of a chronic lithemia and treatment was directed to the relief of this condition.

The next day the face had assumed an anxious expression, the headache was slightly improved, and the epigastric pain considerably increased. A free movement from the bowels followed the treatment of the previous day, and the tympanites was less marked. During the next two days the patient apparently improved with the exception of the epigastric pain, although this was intermittent in severity. The temperature ranged from 99° to 100.4°. On the third day a consultation was held with Dr. E. J. Taggert of Bremerton, who concurred in the diagnosis of lithemia and autointoxication.

On April 27 the patient's condition remained the same and Surgeon D. N. Carpenter, U. S. N., was called in consultation. He disagreed with the diagnosis and suspected typhoid fever, because of the duration of the fever, and the catarrhal symptoms of the gastrointestinal tract. Intestinal obstruction was not considered, in view of the free movement from the bowels three days before. There was no evidence of disturbance of the appendix or gall-bladder. Acute pancreatitis was thought of, but dismissed as the pain was not sufficiently intense, and the patient had been sick for over a week. A Widal examination of the blood was made with suspension culture of sterile bacilli, but the result was negative The strained specimen of the blood showed no malarial parasite or evidence of leucocytosis. The urine was negative and the diazo reaction not present. The next day the symptoms ameliorated and the following two days the patient was considered to be convalescent.

On Sunday, April 30 about 4 P. M., there was a return of the epigastric pain and at 7.30 P. M., while the patient was on the bedpan, he was seized with excruciating pain in the epigastrium with symptoms of collapse. Surgeon Carpenter and I were immediately summoned and diagnosed a severe intestinal hemorrhage. Treatment proved of no avail and death occurred at 10.30 P. M.

A partial autopsy was permitted. Upon opening the abdominal cavity evidence of an extensive hemorrhage was at once seen by the huge blood clots and serous fluid present. Seeking the origin of this hemorrhage the head of the pancreas was found to be indurated, hemorrhagic, and lacerated from the pressure of a large blood cyst that had ruptured. Several small blood cysts remained with clots in various stages of organization. Although the pancreas was enlarged and indurated, no areas of fat necrosis were observed. The omental fat was unusually opaque, and there was also fatty infiltration of the mesentery of the intestines. There was no inflammation or ulceration of the intestines or evidence of obstruction. The appendix and gall-bladder were normal. The heart showed hypertrophy of the left ventricle. The lungs in the dependant portions were edematous. The stomach was normal. The liver on section was fatty. The kidneys were not enlarged and apparently normal. The spleen was enlarged and friable.

The pathological diagnosis of this case is, therefore, a chronic pancreatitis with acute hemorrhage causing death.

## HOSPITAL BUILDING IN THE PHILIPPINE PROVINCES.

By DONALD G. McCASKEY, M.D.,

BUENA VISTA, P. I.

THIRD LIEUTENANT AND MEDICAL INSPECTOR PHILIPPINE CONSTABULARY.

Because of the meager acquaintanceship of the profession in general with what a native-built Philippine bamboo hospital is, the following snap shots and account describing them may be of interest to many readers of the Medical Record.

First of all, Filipino building construction as revealed here at different stages does not essentially vary, and applies to native shacks or houses throughout the islands. Not a nail is used in the entire building. Everything is of bamboo wood, except the heavy foundation posts, a heavy coarse native grass for the roof, called cogon grass, and a native vine called "bayuka" which is used for tying the different joints and joist connections. For the large joint connections there is also used a wooden spike made of bamboo.

When the work is all completed the house is a neat, cosy looking, strong, and rain-proof structure, as cool as can be found anywhere underneath an intensely hot tropical sun.

Described from start to finish the native way of building is as follows: Natives with carabao, commonly called water buffalo, go out into the Philippine "bosque" or jungle, cut bamboo, and have their carabao drag five or six of the bamboo trees back. Carabao move very slowly, natives work more

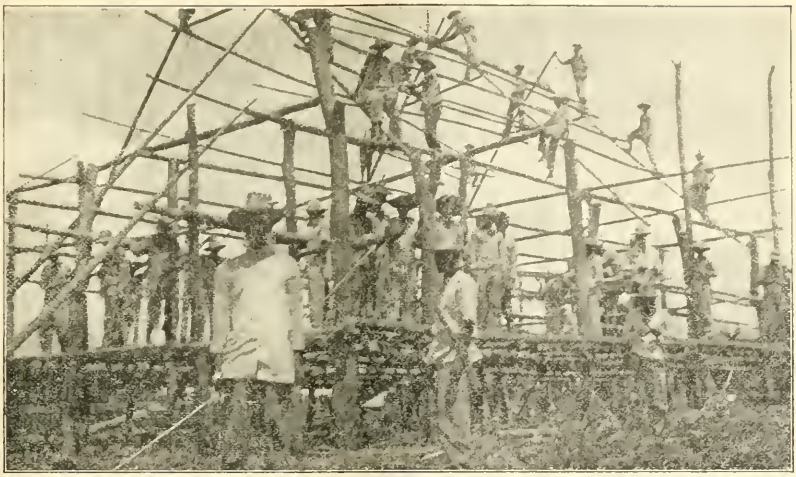


Fig. 1.

leisurely still, the Philippine sun is intensely hot, and one carabao load is considered a day's work.

The hospital pictured herewith, though only twenty by thirty-five feet in size, with a six foot porch around it, required over one thousand separate bamboo trees.

The floor is made of bamboo strips two inches wide and as long as the tree length, placed side by side, and held down by slender bamboo strips running crosswise at intervals of two or three yards. These crosswise strips are tied down with the tying vine, bayuka. This tying material must be stripped, and in the skeleton framework picture (Fig. 1) two natives may be observed preparing the vine for use.

Surprising as it may seem, the grass roofs rarely leak and afford a very comfortable and refreshing degree of coolness and protection from the sun. This cogon grass is cut from the bosque, where it grows in places to a height of twelve to fifteen feet. Its fiber is very coarse and strong, and its edge cuts the hand like a keen-bladed knife if the hand is suddenly slipped along it. Over two hundred bundles are required for this roof.

The grass, after being cut by the natives with their bolos, is sorted into large bundles shaped like wheat sheaves. It is then carried along the trails into town hanging from both ends of bamboo poles, which latter rest on the shoulders of the natives. Each man supports one pole, with from two to four grass bundles suspended from it, and the sight of over one hundred of them traveling along in single file with their freight, is a very curious and interesting one.

To build the Buena Vista Hospital required the services of eighty hombres (Filipino men) for ten full days. In American the same amount of work could and would readily be accomplished in two or three days. "Mañana" is the Filipino policy, and to let his mind wander aimlessly to most every subject except the one in hand. They are good workmen when they feel like working, which is rare, and when they do not have to think and attend closely to what they are doing. It is in doing the things which come easy to him that the Filipino may be useful.

Though no picture is displayed of the interior of

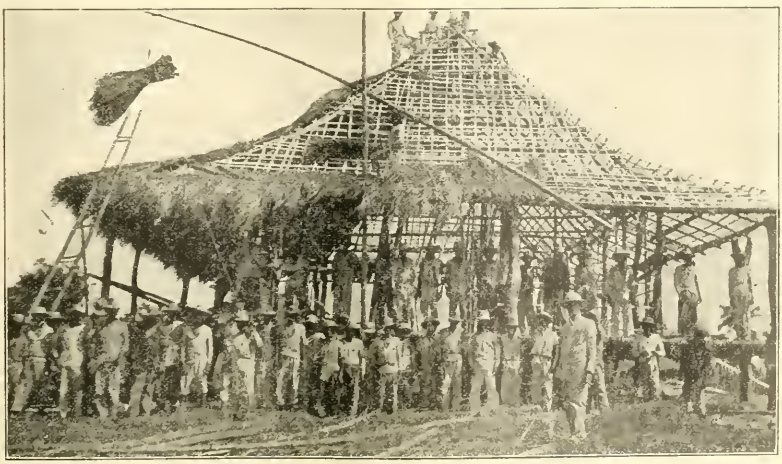

Fig. 2.

Fig. 3.

the hospital here revealed, the deficiency can readily be supplied when it is known that the room area of twenty by thirty-five feet is divided into two rooms, eight by ten feet each, one for sleeping quarters and the other a combination bath and operating room, a dispensary five by ten feet in dimensions, and the remainder one large ward. In place of cots or beds, the above hospital is provided with a continuous bamboo platform elevated two feet above the floor. On this latter the sick lie, the circulating air being able to reach them from all sides.

Besides the window and door spaces for ventilation, the air easily moves through the millions of spaces between the many pieces of bamboo of the flooring and walls, in addition to the foot of intervening space which exists between the top of the walls and the roof. There is barely a stir of air outside the hospital which is not felt within, so free is the ventilation. This matter of ventilation is one of the Filipino carpenter's chief aims, and is among the first things noticed by an American traveling through the islands.

---

**Carcinoma of the Tongue.**—G. E. Armstrong declares that in making a diagnosis of epithelioma of the tongue one must think of simple ulcer, decubitus ulcer, syphilis, tuberculosis, and actinomycosis. In general, it is not difficult to exclude non-malignant conditions. Sometimes, however, this is very difficult for even an experienced clinician. In all of these conditions the microscope should be used to confirm or alter the clinical diagnosis. The two should agree. Operation for carcinoma of the tongue is most serious, and unless the diagnosis is absolutely certain and confirmed by microscopical examination, the writer does not think that the operation should be undertaken. In dealing with this disease all glands communicating with the focus should be removed. If the glands are at all enlarged it should be assumed that they may be malignant. They should be removed with the same thoroughness as those in connection with glandular carcinoma of the breast. The writer does not believe that the whole tongue should be removed in all cases. Recurrence after removal of the whole tongue is nearly always on the same side of the stump or about the tonsil, or in the lymphatic glands of that side of the neck. The object of the operation is to save life from a disease that is always fatal if it is left alone. Partial excision should be considered only in cases in which the disease is recognized early and is limited in its extent. The thorough removal of all the lymphatic glands which have been infected by the disease is most important. The writer concludes by saying that he thinks it would be well if the profession took a more hopeful view of epithelioma of the tongue. It is because the disease in too many cases is not recognized sufficiently early that results are bad; operative procedures, too, have not always fulfilled all the indications taught by the pathologists of to-day, and, besides, physicians have not been careful enough in urging their patients who have warts, fissures, or ulcers on the margins of their tongues, to get an early diagnosis, and when the growth is found malignant, to have it removed. Recurrences are exceptional.—*Montreal Medical Journal.*

**Reversal of the Patella.**—J. Hogarth Pringle records a case of reversal of the patella, occurring, with other serious injuries to the knee joint, as a result of a fall from a building, which necessitated the amputation of the leg above the knee joint. The patella was found lying on the outer margin of the external condyle, pivoting on the outer lip of the trochlea, inclined slightly outward, and it was impossible to bring it back to its position until an incision was made into the aponeurosis, when the cartilage-covered surface of the patella presented, looking forward, and with an elevator, the hip flexed, and after much trouble the bone slipped into place. When the knee joint was dissected it was found that the attachment of the vastus externus had been completely torn from the patella, as well as a part of the rectus and its fibrous expansion. The upper margin had been fractured off, and lay loose in the joint. The patella had been rotated so that the internal border had passed backwards. The author has found only seven published cases of reversal of the patella. In most of these the bone was easily replaced by the use of the thumb and fingers. There are two varieties—those from within outward, where the external margin of the patella passes backwards, the internal going to the front, and those from without inwards, when the external margin passes in front and to the inner side. The last is the rarest, and the recorded case is of this type. It has been found very difficult to produce this type of dislocation artificially, and Streubel gives it as his opinion that it cannot be produced unless there has been a rupture of the capsule of the joint and the extensor expansions. Meyer argues that reversal of the patella is the result of two forces, both of which are tangents to the circle of rotation, brought to play on the margins of the patella; the second force is the resistance of the sloping surfaces of the condyles, when the knee is flexed. The author has experimented with elastic webbing and a rigid band forming an artificial ligamentum patellæ, and finds that the patella is twisted to a varying degree, and may lie in several positions.—*Scottish Medical and Surgical Journal.*

## VISCERAL INVASION IN MAMMARY CANCER.

In cases of cancer of the breast the danger of metastasis is commonly believed to be along the lymphatic chain of the axilla, whence the malignant particles are carried to the supraclavicular glands and so enter the blood-current. This belief is founded upon the fact of the early involvement of the axillary glands, and upon it rests the universal practice of following the lymphatics to the axilla, in operations for mammary cancer, and cleaning out this region. It is thought, too, that the skin affords a ready means for the diffusion of the cancer cells, hence the practice of making wide incisions and removing the integument freely over a broad area around the primary growth.

In a paper read before the Surgical Section of the British Medical Association, at the recent meeting at Leicester, Mr. W. Sampson Handley of London attacked this belief, and expressed the conviction that the embolic transfer of cancer particles along this route was infrequent, or "a mere side issue in the process of dissemination." The diffusion of cancer was effected, he held, mainly by a process of permeation," a spreading growth of malignant cells along the minute lymphatic vessels. If the blood were the main channel of diffusion the thoracic viscera would naturally be invaded more frequently than they are relatively to the abdominal organs. In about 12 per cent. of autopsies the abdominal viscera are found to be the seat of metastasis from mammary cancer, while the thorax is free. This discrepancy is explained by Mr. Handley on his theory of permeation along the fine lymphatics of the body wall. The visceral involvement occurs as soon as this permeation process has reached the lymphatic plexus underlying the pleural or peritoneal endothelium. The cancer cells then escape, says Mr. Handley, into the serous cavities, and attack the serous membrane covering the viscera. Immediately below the ensiform cartilage the subperitoneal fat is separated from the lymphatic plexus of the deep fascia, along which the malignant outgrowth spreads, by the linea alba alone. The epigastric region, therefore, is the weak spot in the defences of the body cavity, and cancer of the breast frequently reaches the peritoneum by this route before it has been able to penetrate the resistant wall of the thorax.

If Mr. Handley is correct in his theory of metastasis from mammary cancer the inevitable conclusion is that the present method of operating in this condition is defective in that it ignores the danger of invasion by the epigastric route. This danger, he says, must be obviated by excising the deep epigastric fascia to a point two inches below the tip of the ensiform cartilage; this involves no technical difficulty and does not add in the least to the risk of the operation. A linear incision, two inches long, running downward over the ensiform cartilage from the circular incision surrounding the neoplasm affords access to the epigastric region, and another linear incision joining the outer part of the circular incision gives access to the axilla. The flaps should be undermined in all directions and a circular area of deep fascia from nine to ten inches in diameter removed, with the pectoralis major, except perhaps the clavicular portion.

The belief that cancer of the breast spreads along the skin is erroneous, in Mr. Handley's opinion, hence he says it is usually sufficient to remove a circle of skin from four to five inches in diameter centered in the primary growth. Theoretically this operation is well devised in that the edges of integument can be readily approximated without tension, hence the danger of sloughing is eliminated; the condition of the flaps is practically unimpaired, and consequently rapid healing, with no febrile complication, suppuration, or pain, is to be confidently expected.

## VEGETABLE JUICES FOR THE TUBERCULOUS.

THE function of a newspaper is to present to its readers an account of the various happenings of the day, apportioning to each event the prominence in position and the space which its importance demands. We have no cavil, therefore, with the papers which devoted several columns of description and editorial comment the other day, to a report by Dr. John F. Russell of this city, of the results of an addition to the dietary of his consumptive patients. There are, unfortunately, few readers of newspapers, that is to say few members of the community, who, if they are not themselves afflicted, do not number among the members of their own families or their intimate friends some one battling for life against tuberculosis. The subject is therefore one of general interest, and fit for discussion in the public press. We do, however, reprehend the method in which the subject was presented by the headliners. Dr. Russell has not found a "new cure" for consumption, nor ever a "new consumption remedy," as one of the medically sanest of the metropolitan papers labeled it, nor do we believe that he would authorize such a designation. He has simply found what may prove to be a useful adjuvant in the therapeutic management of this disease, and only harm can come from calling it a cure or even a remedy. He has for some time been treating tuberculosis along the recognized lines of hypernutrition and fresh air and has met with a fairly satisfactory measure of success in a class of patients to whom the sanatorium treatment is not available. Meeting, however, with certain cases of the apparently curable type in which ill success attended his best efforts, he was driven to the conclusion that there was an unknown something lacking in the prescribed diet of proteids, hydrocarbons, and carbohydrates, the want of which retarded or prevented the cure. This unknown something he was led to believe, by some process of reasoning

which the published report does not explain, to be vegetable juice. The lack was supplied by the addition to the diet of the expressed juices of all the vegetables in the market and also of apples and pineapples.

Theoretically this addition to the dietary is sound, for, as Fernie says in that delightful book "Meals Medicinal," the constitution of vegetable foods is "altogether of a building-up character, as distinguished from animal life (which involves excretions of the broken-down products as part of its being)." It is possible, therefore, that the raw vegetable juices may give just that fillip to the metabolic processes which is needed to ensure assimilation of the proteids, carbohydrates, and fats contained so abundantly in the dietary ordinarily prescribed for the consumptive.

Dr. Russell claims (or is said to claim, in the newspaper reports) to have had eleven "cures" of pulmonary tuberculosis since January 7, when he began to add vegetable juice to the dietary of his patients. We hope he did not really make such a claim, for it is only a wild optimist who would pronounce any consumptive cured in six months, and an assertion of this sort only throws discredit on the reasonableness of the one who makes it. The patient may have taken on flesh, the cough and fever may have ceased (temporarily), and the tubercule bacilli may have disappeared for a time from the sputum—but a "cold" may bring them all back next week. It is claims such as this, made by physicians, which justify the headliners of the lay press in announcing the discovery of infallible cures and raising false hopes in the minds of the incurably ill. It is possible, and we hope it is true, that Dr. Russell has discovered an aid to assimilation which will be an adjuvant to the recognized methods of treatment of tuberculosis, but that is the most that can be tentatively admitted, and even that remains to be proved.

## "IN CORPORE VILI."

The practice of experimentation on human beings for purposes of medical observation is one that has the sanction of antiquity. Herophilos of Chalcedon and Erasitratos of Keos, who flourished about 300 B. C., are both said to have made anatomical studies by dissecting living criminals, while records left by the Egyptian priesthood seem to indicate that anthropotomy was commonly practised by them. At any rate, the story of Cleopatra's experiments in toxicology, with slaves for subjects, has become fireside history, though it is less widely known that the same imperial dilettante, impelled by a curiosity to know at what period of gestation the sex of the fetus became recognizable, caused numerous slaves to be killed at various stages of pregnancy. During the middle ages, condemned criminals furnished the usual material on which neophytes practised capital operations, such as cutting for stone, the victim being set at liberty in case he was fortunate enough to survive the manipulations of the surgeon.

The nature of investigations in which the living human body is used as a test object has changed since then, but numerous studies of this sort, undertaken to throw light on questions of modern medicine, have been reported from time to time. Chief among these, in point of importance and value, were Jenner's classical inoculation experiments on the boy, James Phipps, which, if they had resulted less happily, would, no doubt, have subjected their author to opprobrium as great as the eulogies he actually received. Accounts of many later experiments have reached the public in more or less garbled form, and have given rise to much popular indignation, which, however, has not always been unjustified. A large proportion of the recent work in this field has been devoted to the study of the gonococcus, and while information of great value has been obtained, it is claimed that in only one instance, in which a general infection resulted, were the results of serious import to the patient. Neisser's experiments with syphilitic serum in 1898 have been looked upon with much disfavor, though as the four subjects inoculated were all prostitutes, it is alleged that the fact that they subsequently developed syphilis need not necessarily have been due to the inoculation. Other authors have studied the nature of leprosy, scarlatina, furunculosis, worm infections in children, tuberculosis, etc., in this way, and usually without consequences of serious moment to the patients, while the gain to science has been considerable. It must be admitted, however, that such work has been done almost exclusively by Continental investigators, and that observers in this country prefer to dispense with this method of experimentation.

Pagel, in an article in the *Deutsche Aerzte-Zeitung* of May 15, 1905, says that the fact that in all ages the best physicians have considered it their privilege and duty to test questions of biology and pathology on the persons of their patients justifies the principle in general. There are decided limits to its application, however, he continues, and any experiment which would jeopardize the life or health of the subject is not permissible. Temporary discomforts or slight disturbances need not be regarded as contraindications, but in all cases the permission of the patient must first have been obtained. In dealing with unconscious, insane, or morbid individuals all experiments which might have even the appearance of hastening death or of causing permanent injury should never be undertaken. In spite of the fact that numerous publications have appeared in Germany denouncing the perpetrators of such experiments, he believes that, judged by the above standards, only very few of the observations made on human subjects are of a nature to deserve criticism. This may be very true, but the matter cannot be settled so easily, for it is hardly one admitting of unqualified approval or disapproval, and each observer must decide for himself according to the merits of the particular case and the dictates of his own conscience.

## The Yellow Fever Germ.

A despatch to *The New York Times* on Tuesday of this week announced that Drs. P. E. and John J. Archinard of New Orleans have been for some time conducting a search for the microorganism of yellow fever, and believe that they have now found it. They have not made public announcement of the fact, but have said in private that they thought their search had been successful. Nothing is said of the nature of the parasite except that it is "a minute germ similar to the malarial germ." It is believed by most investigators that when the causative agent of yellow fever is found it will prove to be a protozoan

parasite, this belief being founded upon the fact of mosquito transmission, a certain period of time being necessary after the insect has bitten a yellow fever patient before she can infect a healthy person. There is no such interval necessary, so far as is known, in the case of any bacterial organisms, and so it is assumed that this time is occupied in the sexual cycle of reproduction of a protozoan in the body of the mosquito. The members of the Commission of the Public Health and Marine Hospital Service, working in Vera Cruz a short time ago, thought at one time that they had found the parasite, but Guiteras and Agramonte in Havana showed that the body pictured by them was only an abnormal blood cell. Before this time various investigators had announced the discovery of the causative agent of the disease—Freire a coccus, and Sanarelli a bacillus, and others, other forms, the two former even making protective sera from the use of which they claimed to have had excellent results. None of these alleged discoveries was confirmed by other observers. What the nature of the bodies may be which the Drs. Archinard have found in the blood of yellow fever patients or in the stegomyia mosquito cannot be known until they have published the results of their investigations, and in the meantime it is useless to make any surmises or to discuss the probability of the correctness of their deductions.

## News of the Week.

**The Yellow Fever** at New Orleans is now so well under control that it is believed the epidemic will be extinguished within three weeks. The danger being so nearly over the need for united action is becoming less urgent, and the inevitable disputes are beginning. Dr. Joseph Holt recently charged that the officials were long cognizant of the existence of yellow fever in the city, but suppressed the announcement of the fact. Dr. Kohnke, the city health officer, on learning of this, wrote to Dr. Holt asking for an explanation, and received a note of which the following is part: "In reply to your note, this instant received, I have this to say: You are evidently trying a bluff game, but, whether so or not, you can pop your whip and wade in, for I make to you neither apology nor explanation. I am only sorry you were not present to hear my speech last night." This cannot be characterized as the "soft answer which turneth away wrath," and we fear it is only the beginning of a most unedifying quarrel which will not be confined to Dr. Holt and the health officer. There will undoubtedly be a rigid investigation of the beginnings of the epidemic, which will be very right and proper, but it will be deplorable if it cannot be made without an angry bandying of accusations and counter charges. Mosquitos having been found breeding in the holy water fonts in the Cathedral, an order has been issued that the fonts be kept dry or else that the water in them be changed daily. Many cases of the disease have been discovered in Natchez, Miss., and an investigation shows that yellow fever has prevailed there for over six weeks, or before it was discovered in New Orleans, and all the time Natchez was enforcing the strictest kind of a shotgun quarantine. Gulfport is another town which trusted to the shotgun while the fever was already well established within its boundaries. The total number of cases reported in New Orleans up to Wednesday of this week was 1,832, and of deaths 267. The daily average of new cases is a little over 40, and is steadily declining.

**Druggists Protest Against the Compounding of Prescriptions by Physicians.**—The physician who enters the sick room and who diagnoses the case, administers his own medicines, and, in the event of death, writes the death certificate, is to be attacked by legislative measures if the recommendation of the resolution adopted by the Illinois Pharmaceutical Association at its recent meeting, held in Chicago, is followed. Resolutions were also adopted commending the prosecution of the drug-adulterating pharmacists and the indiscriminate dispensers of cocaine. The editor of the *Western Druggist*, George P. Engelhardt, delivered an address asserting that the dispensing of medicines by physicians is the overshadowing evil in pharmacy. Under the present laws the physician is permitted to provide his patients with his own prescriptions, not only prescribed, but compounded by himself. The pharmacists do not diagnose diseases, nor do they attempt to do so; therefore, physicians, he thought, should not be permitted to compound their own prescriptions. In consequence of Mr. Engelhardt's remarks a resolution was adopted unanimously favoring such legislation as shall require the coroner or other public officer, in case of death ensuing from disease or otherwise, when the physician in attendance has himself dispensed his own medicine, to issue the death certificate in place of the attending physician, thus placing such death in the category of accidental or violent deaths.

**Cottages for Insane Consumptives at the Watertown (Illinois) Hospital.**—Two cottages for the isolation of tuberculous patients are now in course of construction at the Watertown Hospital. These structures will effectually aid not only in the general care of the 1,200 patients but in more humane treatment for those who in addition to their mental affliction are victims of tuberculosis. The cottages were not provided for in the State appropriation, but this additional building was made possible by the economical expenditure of the general funds of the institution. One of the cottages will be for male patients and the other for female. A tent colony will be provided. Large yards will surround the cottages and provision will be made for six to ten tents in each.

**Free Antitoxin.**—Dr. Samuel G. Dixon, Commissioner of the Pennsylvania State Department of Health, has formulated plans looking to the free distribution throughout the State of antitoxin for the treatment of cases of diphtheria when the patients are too poor to pay for the medicament. Two or more distributing stations will be established in every county, and the antitoxin will be furnished on the prescription of physicians in charge of eligible cases. On August 24, for the first time in seven years, no case of diphtheria was reported to the Philadelphia Bureau of Health. A marked falling off in the number of cases has been noted since the city began to supply antitoxin gratuitously to physicians who desired it.

**Faculty Changes.**—The following changes in the faculty of the Medical Department of the University of California have recently been announced: Dr. Alfred B. Spalding, promoted from instructor in obstetrics to associate professor of obstetrics; Dr. John C. Spencer, from assistant to associate professor of genitourinary diseases; Dr. Raymond Russ, appointed instructor in surgery; Drs. J. Wilson Shiels, Rachel Ash, Milton B. Lennon, and George Blumer, assistants in medicine; Dr. Rawlins Cadwallader, assistant in obstetrics; Dr. A. J. Lartigau, assistant in gynecology and pediatrics; Drs. H. P. Robarts, Camillus Bush, and Jacob Schwartz, assistants in surgery; Dr. Howard Morrow, promoted from assistant to instructor in diseases of the skin,

and Drs. Lionel L. Schmitt, Harry E. Alderson, and Florence McCoy Hill, appointed assistants in diseases of the skin.

**Medical Colleges in Illinois.**—According to the *Journal of the American Medical Association* of August 19, Illinois, with a population of 4,821,550, has thirteen medical colleges, all located in Chicago, a city of about 2,000,000 inhabitants; they are as follows: Rush Medical College, Northwestern University Medical School, Hahnemann Medical College, Bennett College of Eclectic Medicine and Surgery, College of Physicians and Surgeons, Hering Medical College, Jenner Medical College, Illinois Medical College, American Medical Missionary College, College of Medicine and Surgery, National Medical University, American College of Medicine and Surgery, and Dearborn Medical College. Colleges in Illinois have to admit students in conformity with the minimum requirements of the Illinois State Board of Health, as follows: "A diploma or certificate of graduation from a high school; or a certificate signed by a principal of a regularly organized high school or by the examiner of the faculty of a recognized literary or scientific college or university, or by the State Superintendent of public instruction, or a superintendent of public schools, of having successfully passed an examination in all the several branches embraced in the curriculum of a four years' high school course. The matriculation examination shall not be conducted by any member of the faculty of the medical college. The Illinois State Board of Health will require each applicant for a State certificate to present documentary evidence of his preliminary education, together with his medical diploma, when taking the examination of the board."

**A New Medical School,** called the Nebraska College of Medicine, has been established at Lincoln, Neb. Twenty-seven of the physicians of Lincoln compose the faculty. It is announced that the new college, which will form part of the Wesleyan University, will have courses in Medicine, dentistry, pharmacy, and nursing.

**Failure of the Arsenic Treatment of Yellow Fever.**—Dr. Reginald Leach of St. Paul, Minn., who went to New Orleans to test his arsenization theory—that the taking of arsenic in small doses for two weeks will render a person immune against yellow fever—has failed to substantiate his contention, and has abandoned his experiments. A formal letter was issued to the press, signed by Surgeon J. H. White of the U. S. Public Health and Marine Hospital Service and by the President and advisory committee from the Orleans Parish Medical Society, telling how patients were under treatment for yellow fever who had partaken of the arsenic diet for the supposed sufficient period to render them immune, thereby overthrowing the claims made by Dr. Leach. It is said that 60,000 persons had become temporary arsenic eaters, led thereto by the confident assertions of acquired immunity made in the newspapers.

**Cholera in Prussia.**—A despatch from Dantsic states that two Russian raftsmen recently died at Culm, West Prussia, of what was diagnosed as Asiatic cholera. All Russian raftsmen there have been detained or isolated, and measures are being taken to prevent the spread of the disease. An investigation by the Prussian health authorities confirmed the presence of the disease, but it is believed that there is no danger of the spread of the disease westward. It has existed in certain provinces of Russia for several months.

**Opposed to Medical Control.**—Gov. Herrick of Ohio is said to be opposed to professional control of the benevolent institutions in the State. Former Governors, notably the late Governor Nash, regarded the benevolent institutions as practically belonging to the medical profession, and provided that a majority of the members of all the Boards of Management should be physicians. The latter have since been quite generally supplanted by business men. It is now proposed to treat the State Hospitals in the same way. Although these institutions were established and brought to their present state of efficiency by the physicians of the State (the Ohio Lunatic Asylum, opened in November, 1839, with a capacity of 120, had its origin in a memorial adopted and sent to the Ohio Legislature by the Ohio Medical Society in January, 1835), the medical profession is now but little represented on the managing boards, its counsels are entirely ignored, and the plan has been formulated and will soon, it is said, be put in operation to take from the medical superintendents of the hospitals all executive control.

**Hospital Corps Ohio National Guard.**—By orders just issued by the Adjutant General's office, the Second Company of Instructions, Hospital Corps, Ohio National Guard, stationed at Columbus, is changed to Ambulance Company, Section No. 2, the change being effective immediately. The entire Hospital Corps organization of the State is changed to make it more nearly conform to the field service regulations of the United States Army.

**Dr. Joseph Herbert Ford,** of the U. S. Army, recently stationed in Oklahoma, has been compelled to undergo an operation for appendicitis at the General Hospital, San Francisco. The latest report is that he is recovering rapidly. It is his intention, it is said, to sail for the Philippines on October 5, where he expects to make further study of the serum treatment of malaria. A preliminary report of his work in this direction appeared in the MEDICAL RECORD of December 24, 1904.

**Dengue in Florida.**—Dr. Joseph Y. Porter, Health Commissioner of Florida, has sent a circular letter to the physicians of the State warning them of the presence of dengue in several cities. The disease appeared first in Key West and spread thence to Port Tampa and Tampa. The mortality from the disease has been nil.

**No Leprosy at Oakland.**—A report recently circulated, to the effect that a family that had recently arrived from Honolulu was afflicted with leprosy has been investigated and found to be entirely without truth.

**Cholera at Manila.**—Some of the soldiers at Camp McKinley and several citizens in Manila, twenty-five in all, have died in the past two weeks of this disease. There were forty cases up to August 29.

**The National Negro Medical Association** held its third annual meeting in Richmond, Va., on August 22 and following days under the presidency of Dr. John Hunter of Kentucky. The opening session was called to order by Dr. R. E. Jones of Richmond, and an address of welcome was delivered by Mayor McCarthy. The next meeting will be held in Philadelphia. Dr. Jones was elected president for the coming year.

**Laboratory of the Board of Health.**—The new bacteriological laboratory of the Health Department has recently been opened. The building has been in process of construction for several years. It is attached to the old Willard Parker Hospital for contagious diseases in East Sixteenth street.

**Obituary Notes.**—Dr. JAMES HENRY SALISBURY died at his home in Dobbs Ferry, N. Y., on August 23, after a long illness. He was born in Scott, Cortland County, N. Y., in October, 1823, was graduated from the Troy Polytechnic Institute in 1846, and

from the Albany Medical College in 1852. He practised for a time in Cleveland, Ohio, and later moved to New York City. He was an accomplished microcopist and a member of many scientific societies. For many years he had devoted himself to the study and management of chronic diseases.

Dr. William Nutter of Malden, Mass., died August 17, after a long illness, at the age of forty-three years. He was born in Montreal and was graduated from the Medical Department of the University of Vermont in 1887. He was for three years City Physician in Malden, in which place he practised seventeen years.

Dr. J. W. Mooar of East Manchester, N. H., died August 18 at the age of sixty-seven years. He was born in Hollis and was graduated from the Dartmouth Medical School in 1862. He at once joined the medical corps of the army and served throughout the Civil War. He began practice in Manchester in 1867.

Dr. L. M. Willis of Bartow, Fla., died August 4, at the age of seventy-seven years. He was born in New York State and served during the Civil War in the medical corps of the Union Army. He removed to Tennessee in 1870, and later went to Hutchinson, Kans., where he remained until 1884, when he went to Bartow, retiring from practice at the time on account of feeble health.

Dr. L. J. Frazee of Louisville, died of pneumonia on August 12 at the age of eighty-six years. He was born in Mason County, Ky., and was graduated from the Medical Department of the University of Louisville in 1841. After a course of study in Europe he began practice in Maysville, moving later to Louisville. He was formerly in the faculty of the Kentucky School of Medicine and of the Medical Department of the University of Louisville, and for a number of years was editor of the *Transylvania Medical Journal*. He retired from practice several years ago.

Dr. Robert M. Stone of Omaha, Neb., died August 14. He was born in New York State and was graduated from the St. Louis College of Physicians and Surgeons in 1884.

Dr. Marcellus H. Felt of Hillsboro Bridge, N. H., died August 21 at the age of sixty years. He was a graduate of the Dartmouth Medical School in 1877. He was for many years treasurer of the New Hampshire State Medical Society and was its President in 1904.

Dr. Edward W. Shead of Seattle, Wash., died August 20 as the result of a fall. He was born in Eastport, Me., and was graduated from the Harvard Medical School in 1903.

Dr. Robert W. Hynds of Atlanta, Ga., died of typhoid fever on August 18, at the age of twenty-six years. He was a graduate of the Medical Department of Vanderbilt University.

Dr. William D. Pettus died at his home in Rep, Ala., on August 13, at the age of sixty-two years. He was a graduate of the Medical Department of the University of Nashville in 1868.

Dr. Morris Rogers of Deadwood, S. D., died suddenly on August 20, at the age of sixty-seven years. He was born in Kentucky and was graduated from the Medical Department of the University of Iowa in 1869. He had practised in the Black Hills since 1878.

Dr. Will Rininger of St. Louis, died at his home on August 22, as a result of burns received from the explosion of benzine while working in his laboratory. He was born in Tiro, O., and was thirty-two years of age. He graduated from the Marion-Sims Medical College of St. Louis in 1899. He was assistant to the chair of nervous diseases at the Marion-Sims Medical College, and chief of the clinic of nervous diseases at St. John's Hospital. He was a member of the St. Louis Medical Society and the American Medical Association.

Dr. Henry D. Stauf of St. Louis disappeared from his home on July 28 and on August 12 his body was taken from the Mississippi river at Barrows, Tenn. Dr. Stauf had been in poor health for some time and it is supposed he wandered to a favorite fishing resort near Barrows and was accidentally drowned. He was forty-two years of age. He was graduated from the Missouri Medical College (Medical Department of Washington University) in 1885.

## Correspondence.

### OUR LONDON LETTER.

(From Our Special Correspondent.)

IS ISOLATION TO GO?—PHYSICAL DETERIORATION—DEATHS OF CHRISTOPHER HEATH AND JOHN WILLIAM OGLE.

London, August 11, 1905.

Many have long suspected, and not a few have been convinced, that our system of hospital isolation in infective diseases is a huge failure. There are murmurings, too, among the public that they have been induced by sanitarians to enter on an extravagant and even disastrous course. Enthusiastic advocates of the system are reconsidering their position, and the reaction was well exhibited at Leicester, when, after a pretty full discussion, a resolution was agreed to requesting the Local Government Board to institute an exhaustive inquiry into the whole subject.

Dr. George Wilson, whose experience as a medical officer of health extends over thirty-two years, opened the discussion with the confession that he was at one time strongly in favor of hospital isolation for the benefit of the community, and welcomed the Act of 1893, though he regarded it as defective because it did not extend to small towns except by consent. But experience has changed his views. As to smallpox, he thought hospitals could be dispensed with if vaccination and revaccination were generally practised, even as in Germany there are no such hospitals.

Dr. Wilson then presented statistics as to scarlet fever in his district, showing no material difference between places with and without hospitals, the obvious inference being that isolation after years of trial has utterly failed in controlling the incidence or moderating the death rate of that disease. He thought slight cases had a better chance of recovery in their own homes, and the risk of infection to the household was less than is generally supposed.

Dr. Whiteside Hime, one of our foremost medical officers of health, followed with a paper in which he said twenty-five years' experience of isolation compelled a reconsideration of the matter. Illustrating the progress of preventable diseases by a number of charts, he showed there was no evidence of any controlling power, and this was the case in regard to all preventable diseases. In Leicester itself, when ninety-eight cases of scarlet fever were sown broadcast in the population to make room in the hospital for smallpox cases, there was no increase of scarlet fever, but actually a decrease in the next six months.

Dr. O'Connor, M.O.H. for the thirteen Leicestershire combined districts, followed. His statistics showed that during the last three years the rural district which suffered most from scarlet fever was the one that applied hospital isolation most completely. The disconcerting conclusion that isolation had utterly failed had to be admitted. Further, he had observed that children who had safely passed through the original infection had not been able to resist a recrudescence of an epidemic.

Dr. Waddy of Sheffield devoted a paper to return cases. His statistics showed that returns within fourteen days were half as many again in hospital treated than home treated, and after fourteen days the proportion rose to twice as many.

Dr. Marsden (Birkenhead) took up the cudgel on the other side, and said the arguments of the four papers amounted to the suggestion that if they took an infective center away and isolated it they did more harm than good, and this he thought preposterous. What the statistics did show was that we know nothing of the infection of scarlet fever. It is knowledge of the disease that is at fault—not isolation hospitals.

Professor W. R. Smith had a strong impression that sta-

tistics would not settle the question. He was for impartial inquiry.

Three or four other speakers discussed case mortality, and some said whatever statistics might point to, hospitals had come to stay, though more complete isolation would so increase expense that the rate-payers would have a say in the matter.

As I said above, an inquiry by the Government Board has been asked, and Dr. Willard remarked that some years ago he had proposed such a resolution, which was shelved by the "previous question."

In connection with the foregoing discussion, I may mention the proceedings of the Asylum's Board's last meeting. It was stated that 21,000 cases of scarlet fever and 538 of smallpox had been admitted to the board's hospitals in 1904. The mortality rates of scarlet fever and diphtheria were slightly higher, but typhoid fever showed a decrease. The mortality from diphtheria had fallen from thirty in 1893 to ten last year. The annual expenditure on cases of mistaken diagnosis was said to be about £12,000, an average number of 2,000 being admitted who ought not to have been sent, and of course such persons were exposed to risk of infection. A joint report of the superintendents of the hospitals stated that most of the patients discharged should be sent home in vehicles exclusively reserved for that purpose. There was further some consideration of a proposal to establish a motor ambulance service at the cost of the ratepayers, to supersede the one supported by voluntary contribution.

The subject of physical deterioration, so much discussed of late, was bound to come up at Leicester. It was introduced by Dr. Dawson Williams, who had no doubt of its existence at various ages, though mainly noticeable in children, and chiefly those of the working classes, and therefore attributed by some authorities to bad housing, overcrowding, unsuitable feeding, etc. He also admitted that there is evidence that the infants of mothers who work all through their pregnancy weigh less than others; so that it would be interesting to know whether preventing women working during pregnancy would really prevent them from obtaining adequate food. Intemperance in the father was more injurious than in the mother. Though much has been done to improve the public health, there remains much to be done. Dr. Williams did not think we can express an opinion as to the real cause, but we know the fact that children born in the poorest districts weigh less and grow up smaller in stature than those born in better localities.

Dr. Hall of Leeds said many causes were talked about, but the real cause was poverty. Fifty years ago the poorest mothers were cleaner, more sober and more domesticated. This had been done away by our boasted civilization and elaborate educational schemes. At a cost of twenty millions a year we have swept the poor man's children into schools, and he is unable, if his family be large, to provide properly for them single handed. Formerly the mother stayed at home. Now she often has to go out to work, with the result that the children are not properly cared for and are fed on most injurious food, spiced with pickles and condiments.

Dr. Spanton blamed the fashion of the age. A life of pleasure, he said, is the root of the evil. Life to-day is too full of excitement, too full of pleasure, too full of leisure, too full of hurry, too full of everything except honest work. We hear of the dignity of labor, but those who say most about it seem the most anxious to avoid it. What is wanted is to go back to a simpler life, and the rich as well as the poor need the same.

Dr. Rutherford said the twenty millions for education grudged by one speaker was small compared with the 160 millions spent on alcoholic drinks—the most serious thing for the working classes. He wanted a Minister of Public Health in the Cabinet.

Dr. Langley Browne said his large experience led him to conclude that deterioration did not begin until from thirteen years of age, and from that to eighteen the development was not kept up; in fact he thought development had improved up to about thirteen, and that accorded with the cheapness of food. Between thirteen and eighteen smoking and drinking came in and arrested development.

Two of our senior leaders have passed away this week—a consulting surgeon and consulting physician to their respective hospitals after long service, and each having held high offices in their respective colleges.

Mr. Christopher Heath died suddenly on Tuesday in his seventy-first year. Though you will remember him as for many years connected with University College, he was originally a King's College student, and took his M.R.C.S. in 1856. Four years later he was admitted to the Fellowship of the College of which he became president in 1895, having been examiner, lecturer, and Hunterian orator. He had also been examiner in surgery at the Universities of London, Cambridge and Durham, as well as at the College of Physicians. After full service as surgeon he became consulting surgeon to the hospital in 1900, and Emeritus Professor of Clinical Surgery to the College. He had held, too, a number of other appointments and honors. His "Operative Surgery" reached a second edition in 1884. His "Manual of Minor Surgery" ran through twelve editions by 1901; "Practical Anatomy" eight editions by 1903. Of his other works, the Jacksonian prize on "Injuries and Diseases of the Jaws" and his "Intrathoracic Aneurysm," 1871 and 1898, are the most important. He edited a "Dictionary of Practical Surgery," 1886.

On the same day died John William Ogle, consulting physician to St. George's Hospital, at the age of eighty-one. He was an Oxford man, M.A. 1851, M.D. 1857, F.R.C.P. 1855. He had been Croonian lecturer, Harveian orator, Censor and Vice-President of the College of Physicians. He had served both the old universities as an examiner, and in his long association with St. George's Hospital he filled many posts and always with distinction. He did much for the museum, put its catalogue in an excellent state, and was joint editor of the printed volume as well as of the "Hospital Reports." He was Vice-President of the Medico Chirurgical Society, to the *Transactions* of which he contributed valuable papers, as he also did to other societies and journals.

## OUR VIENNA LETTER.

(From Our Special Correspondent.)

DEATH OF PROFESSOR NOTHNAGEL—EHRLICH'S ALDEHYDE REACTION—MECHANISM OF GASTRIC PERISTALSIS—DIFFERENCES BETWEEN THE FAT OF INFANTS AND OF ADULTS.

VIENNA, July 31, 1905.

THE month of July has been one of mourning for the medical profession of Vienna, for on the seventh of the month Professor Hermann Nothnagel died at the age of sixty-six years. The loss of Nothnagel is a calamity not alone for the faculty of which he was so distinguished a member, but also for our entire profession. His reputation had extended over all the world, so that thousands of patients from all countries came to seek his advice. He held the chair once filled by Skoda, and served mankind in the manner laid down by that master. Like Virchow he came from the German Friedrich-Wilhelms Institute, and he there profited by the influence of his teacher, Traube. Whereas Traube concerned himself especially with the diseases of the vascular system, Nothnagel early devoted himself to the study of cerebral and nervous diseases, and those of the digestive system, and while still young he enriched this chapter of medicine with many important observations. He was graduated in 1863, and from 1865 to 1868 was v. Leyden's assistant at Königsberg. From 1868 to 1870 he served as Dozent and military surgeon in Berlin. He took part in the first battles of the Franco-Prussian war, but was then incapacitated by an attack of typhoid fever and had several relapses. The years from 1870 to 1872 were spent in Breslau, and he was then called to Freiburg in Breisgau to assume the chair of materia medica. He contributed largely to the experimental development of this branch, and his text book on this subject, produced with the collaboration of Professor Rossbach, has run through many editions and is a classic in pharmacology. He went to Jena in 1872, and the ten years spent there with his family and in the company of the most eminent scientists were among the happiest of his life. In 1882 he was called to Vienna as Duchek's successor in Skoda's clinic, and held his first lecture on October 16. In this he eulogized the achievements of his predecessors and praised the spirit of humanity which lends the ethical value to our science. It was on this occasion that he uttered his famous dictum that only a good man can be a good physician. Nothnagel was one of the most beloved of the Viennese teachers, and his brilliant delivery, the magnetism with which he inspired his listeners, and the masterly manner in which the phenomena of disease were analyzed caused his lecture room always to be filled with students and physicians.

At the meeting of the Society for Internal Medicine, Dr. Bauer read a communication on the subject of the Ehrlich aldehyde reaction in the urine and feces. This is carried out as follows: A few c.c. of urine are mixed with several drops of 2 per cent. solution of dimethyl paramidobenzaldehyde in 20 per cent. hydrochloric acid, and a little extra hydrochloric acid is added. In normal urine a slight red color is produced, which in pathological specimens becomes intensified and is associated with a band between the D and E Frauenhofer lines. The reaction is produced, as Neubauer first pointed out, by the urobilinogen present in the urine. The reaction disappears on the conversion of the urobilinogen into urobilin. Urobilinogen produced from urobilin and bilirubin also gives a distinct reaction with Ehrlich's aldehyde. The urine used must be fresh, as otherwise the urobilinogen is easily reduced on exposure to the air. In freshly passed urine urobilinogen is present to the almost complete exclusion of urobilin. Ehrlich's reaction is a simple test for urobilinogen and is positive in all diseases,

particularly those of the liver, in which urobilinuria has been observed. In biliary fistulæ and obstruction of the common duct urobilinogen and Ehrlich's reaction are absent from the urine, and it therefore appears that this substance originates in the intestine. Tests for urobilinogen and Ehrlich's reaction should always be performed in conjunction with each other, as the latter may be caused by the drugs or other undetermined substances in the absence of urobilinogen, and in some cases in which this principle is present, as in glycosuria, the reaction may be negative.

Dr. Rudolph Kaufman presented before the same society a new theory of the mechanism of gastric peristalsis. It has been supposed that in this peristalsis the stomach contracted progressively towards the pylorus. Beaumont, however, showed that a constriction is formed which divides the pylorus from the fundus. Kaufman experimented in this connection by using curarized dogs which were also under the influence of morphine. A glass tube was carried through the esophagus into the stomach, and another through the pylorus. Water flowing through the first emerges from the second, but on stimulating the vagus the flow is checked suddenly, showing that a water-tight septum must have formed in the stomach. By inserting needles it was possible to prove that the partition was situated at the junction of the pylorus and fundus. It is probably due to the contraction of the oblique muscle fibers of the abdominal wall which twist the stomach in opposite directions about with its axis, so that occlusion must occur.

Dr. Lehndorff and Dr. Knöpfelmacher have made interesting observations on the fat of infants. Adult fatty tissue is soft, yellow, and has fat droplets on the cut surface, whereas that of infants is white and shows no droplets. The fat itself in adults is fluid at room temperature and is yellow, but that of infants is white and firm and melts only at a temperature of 40° C. These differences are due to variations in chemical composition, for infantile fat contains 67 per cent. of the fluid oleic acid and 33 per cent. of the solid stearic and palmitic acids, while in adult fat there is 90 per cent. of oleic acid. According to Knöpfelmacher the oleic acid increases in amount from birth on, and at the age of two years reaches the adult proportion. In emaciated children the oleic acid is increased. In a new series of observations the authors have sought to find the explanation of the discrepant results obtained by other observers in this connection, and have come to the following conclusions: The fat of the newly born infant contains about 50 per cent. of oleic acid, and this quantity gradually rises until at the second year it is about 72 per cent. and approaches the fat of adults. At the same time the melting point drops from 40° to 45°, to a much lower figure. The fat of breast-fed children is richer in oleic acid than that of those artificially nourished. The cause of this is that the fat of human milk contains more oleic acid than that of cow's milk, that is, it seems that the composition of the fat depends on the nature of the food. In intestinal catarrhs and all diseases in which there is loss of body weight there is also a decrease in the oil component of the fat. Free fatty acids are also found in the fat, but their quantity does not appear to be related to the food or state of health. The composition of the fat remains constant to the ninth month of life, as until then the infant is fed exclusively on milk. The high melting point of the fat of nurslings underlies the fact that sclerema can occur only in little children, owing to a fall in temperature sufficient to permit tha fat to liquefy.

---

**Prolonged Lavage a Preventive of Ether-Vomiting After Operation.**—George S. Brown assumes that it is the presence of ether in the system that causes the vomiting after operation by its direct effect on the vomiting center in the brain or its irritant effect on the stomach. He considers the appropriate treatment of the condition to be the washing of the ether out of the blood as rapidly as possible. Much of the ether is eliminated by the stomach, and if lavage is begun before the patient becomes conscious, and is continued for some time, the ether is rapidly eliminated and the vomiting is avoided. When the ether is all out of the blood, vomiting ceases; but this may require three or four days. The patient should be kept well under ether so that the tube can be introduced without causing retching. The lavage is continued until two and a half gallons of water have been introduced and removed. The last wash water will not smell of ether, the sleep will pass off in an hour or two, and at the end of twelve hours the breath will not smell of it. During the last three years this method has prevented ether vomiting absolutely in the author's cases.—*Surgery, Gynecology, and Obstetrics.*

**The Localization of Chronic Suppurations of the Urinary Tract.**—Arthur L. Chute says that a careful localization of chronic urinary suppurations is essential for accurate treatment and the conclusions drawn from the glass-tests, as applied to suppurations of the urethra, are often misleading, while those drawn from the irrigation test are more accurate. Without cystoscopic examination, it is at times almost impossible to differentiate chronic suppurations of the bladder from those of the kidney. Before operating upon a suppurative lesion of the kidney it is essential that one verify his diagnosis as to which kidney is involved, either by seeing turbid urine issuing from the corresponding ureteric orifice or by ureteral catheterization, and reliance upon symptoms alone, even when these seem to leave no doubt, may lead to serious error.

*New York Medical Journal, August 26, 1905.*

**Astigmatism, a Cause of Vomiting in School Children.**—Aaron Brav says that it is known to every practitioner that some children, during their school term, have regular attacks of vomiting, the primary cause of which is often obscure. These children, who go through a season of school life with dizziness, nausea, headaches, and vomiting, and have all the symptoms of anemia, are often treated for it without good results, and the only thing that gives them relief is the keeping them away from school environment for a few weeks. In considering the treatment of this condition it is essential that the primary causal factors be established and removed, if possible, and in determining the original cause of vomiting in school children one should think of the possibility of a faulty anatomical construction of the ocular refractive media. From a few clinical cases reported, and such are not infrequent, it will be noticed that the histories were nearly all alike, and the primary cause could be determined only by a careful urinary analysis and a thorough examination and search for ocular defects. The cause determined, the error corrected was followed by recovery which was complete, except in one case, and here complete recovery could not be expected from a chronic form of nephritis. The toxic form of vomiting is the only one simulating the vomiting due to astigmatism, and, of course, can only be differentiated by a urinary examination, which both the physician as well as the ophthalmologist will do well to bear in mind. In the absence of kidney conditions, in the absence of gastric pain, in the absence of fever, chills, epigastric fullness, all cases of vomiting in school children preceded by dizziness and headaches and visual disturbances, one can safely prognosticate a probably astigmatic error or refraction as the prime cause, and refer the case to an ophthalmologist for the proper correction of the ocular defect which is responsible for the suffering of the child.

**Preoperative and Postoperative Treatment of Surgical Cases.**—John Egerton Cannaday says that the preoperative and postoperative care of surgical cases is not secondary even to the technique of the operation itself. The value of habituation of the patient to the bed, giving a restricted non-putrefactive dietary, the alimentary canal emptied and put in good condition, the eliminative organs inspected, and normal action if possible secured, the lowered states of resistance as far as practical remedied, is inestimable. Shock may sometimes be averted and well treated by artificial heat and stimulants, of which the chief are physiological saline solution and adrenalin. One should empty the stomach and keep it so to prevent the vomiting. The devotion of special care to the cleansing of the site of incision on skin or mucous membrane is important. After the operation, conserving the energy of the patient in every possible way and avoiding needless purgation and unnecessary annoyances of all sorts are self evident procedures, as are the prevention of tympany by proper dietetic measures and the avoidance of opiates. The value of physiological therapeutics in the management of the convalescent need not be insisted upon.

**Sterility in Women: The Pathological Affections of the Ovaries and Tubes that Produce It, and Their Treatment.**—J. Riddle Goffe considers the intraperitoneal causes of sterility in women, or those which can only be reached by penetrating the peritoneum. The various pathological conditions that obstruct the passage of the ovum into the uterus he considers under three heads: (1) Those that relate exclusively to the ovary; (2) those that relate exclusively to the tube, and (3) those in which both the ovary and tube are involved. The ovary may be absent or it may be congenitally in so rudimentary a state of development as to be devoid of Graafian follicles or incapable of developing them. The most common affections are those that result from inflammation, such as atrophy,

cirrhosis, and cystic degeneration. Cirrhosis of the ovary is usually a process consequent upon an acute oophoritis and is a form of chronic hyperplasia of the connective tissue stroma, by which the follicles are compressed and eventually destroyed. The most frequent pathological conditions that are the cause of sterility in the tube are catarrhal, gonorrheal, and septic salpingitis, pyosalpinx, hydrosalpinx, and hematosalpinx which contorts the tube, giving it so tortuous a course at the flexure that it may become absolutely constricted. The most common condition is one in which the fimbriæ becomes agglutinated and the patency of the tube absolutely destroyed. Cases of atrophy of the ovary are beyond the pale of surgical interference. Hypertrophy and cystic ovaries are to be relieved only by surgical interference. In cases of tubal trouble operative procedures seem to be more efficient. The function of the tube is more mechanical than physiological, and mechanical contrivances are more amenable to mechanical interference. Where the fimbriæ are inverted and adherent, it becomes a simple matter, under a saline douche, to massage the tubes, rotate them between the fingers, and by gradually milking them out from the horn of the uterus to their extremity, gradually to unfold the fimbriæ and restore the ampulla to its normal condition. This is far better than amputating the tube. In cases of acute or chronic salpingitis a nd the long-standing destructive effects, now quiescent, of inflammatory invasion no longer producing symptoms or palpable by the examining finger, the peritoneal cavity is invaded for the deliberate purpose of relieving the condition of sterility and rendering the patient fruitful. Just what the scope and limitation of conservative work upon the tube may be in the presence of retained pus is still awaiting the decision of further experience. He protests against the indiscriminate sacrifice of tubes that are the seat of ectopic gestation. Rupture of the tube and hemorrhage in these cases is not always produced by distention of the tube, but the biological process inherent in the growth of the ovum and placenta erodes the epithelium and eats its way or grows through the wall of the tube and its peritoneal covering. Such cases are peculiarly adapted to such conservative work as opening the tube, evacuating its contents, and stitching up the incision.

**A Contribution to the Study of Chronic Nicotine Intoxication of the Nervous System.**—F. Robbins says that, theoretically, tobacco tolerance might be produced in either of two ways: (1) By compensation, through the formation of antitoxins in the organism, or (2) by a destruction of the poison through oxidation. In view of the fact that aggravation of minor symptoms due to the habitual use of tobacco is so frequently coincident with suboxidation caused by independent factors, the latter hypothesis would seem the more probable one. There is little doubt that the secret of its hold upon the user lies in its retardation of the metamorphosis of nitrogenous tissues. Like alcohol, tobacco retards tissue waste; and that is all that humanity instinctively craves for. The histories of two patients are given as an illustration of what is meant by failure of accommodation on the part of the nervous system to the habitual use and absorption of the tobacco alkaloid. In the selection of these two cases care was taken to limit the discussion of chronic nicotine poisoning to individuals who had used tobacco for periods extending over thirty-one and thirty-nine years, respectively. During the maintenance of fair general health the adjustment of the nervous system to the alkaloid seemed perfect, or nearly so, whereas the phenomena of failing nervous vitality due to the absorption of nicotine came to the front as soon as an additional nux from within or without turned the balance beam, as it were, and interfered with accommodation.

**The Natural and Artificial Protection of Man Against Tuberculosis.**—F. L. Figari says that it is now affirmed that if we have not succeeded in immunizing animals against tuberculosis with living cultures, it is experimentally ascertained that we can produce this immunity by injecting subcutaneously, or administering by the mouth, specific substances taken from animals treated for that purpose. As serum, blood, and milk have this property, certainly the flesh of these animals will possess it. These for the present are the sole means on which we can count for the cure of tuberculosis, by rendering immune the children of tuberculous people and individuals who are predisposed to it. It is only by widely practised preventive immunizing that we can hope to stop the spread of tuberculosis.

*American Medicine, August 26, 1905.*

**What Action Should Be Taken To Suppress Smallpox.**—H. M. Bracken urges that the Conference of State and Provincial Boards of Health of North America put itself on record as follows: Believing that all attempts to restrain smallpox by means of quarantine in a community not protected by vaccination will fail; that rigid quarantine in a well-vaccinated community is unnecessary; that the attempt to control the spread of smallpox by means of quarantine is unscientific, irrational, unsuccessful, and misleading; that in laying down strict rules for the quarantine of smallpox, sanitary authorities are favoring unscientific and illogical methods and are conveying false ideas as to safety, this conference protests against further attempts to control smallpox by means of quarantine and requests the passage of compulsory vaccination laws similar to those of Germany, requiring (1) the compulsory vaccination of infants, (2) revaccination at puberty. The conference should further place itself on record as requesting that steps be taken to secure a safe and efficient vaccine, and that vaccination be carried out by official vaccinators acting under the authority of the various Boards of Health; also that steps be taken to secure a vaccine the quality and efficiency of which are beyond question. Legislators and the people should be advised as to their responsibilities in suppressing smallpox, and a time should be set for the total abandonment of quarantine as a means of attempting to control this disease.

**Nature and Cause of Hunger, Appetite, and Anorexia.**—Mark I. Knapp says hunger is the sensation produced by the contraction of the muscularis of the pylorus, of the entire stomach, of the duodenum, or of all these structures. It is the contraction of the muscularis, most especially the contraction of the pylorus, which, when felt in not too intense a degree, is interpreted as hunger. If the contraction is more intense it is felt as a painful hunger. If the contraction is of a slight degree then the sensation of the hunger is also of a slight degree, it is evanescent. This is the reason the hunger passes away after a certain lapse of time, even if no food has been taken; it means simply that the contraction has given way to relaxation. A "hearty" appetite should not be encouraged. Such an appetite must be considered as pathological and must be suppressed by the physician, as it is caused by a stronger contraction, hence greater irritation of the mucosa, which should not be. Absence of contraction, the inability to contract, relaxation, distention—these being the opposite, the reverse of contraction—result in the opposite of appetite, anorexia.

**To What Extent Is Climate a Negligible Factor in the Treatment of Pulmonary Tuberculosis?**—W. L. Dunn states that since the dietetic-hygienic regimen may be much more thoroughly and efficiently conducted under certain climatic conditions, climate is a negligible factor only: (1) When the financial status of the patient is such that he cannot live in the health resort under conditions just as good as those obtainable at home, with or without the expenditure of the same amount of money; (2) when the patient has not the moral strength to make a business of getting well; (3) when the disease has become hopelessly advanced.

**The Medical Treatment of Excess of Uric Acid in the Urine.**—Byron Robinson says the rational treatment of excessive uric acid in the urine consists in the administration of ample fluids at regular intervals and of foods containing elements to produce basic combinations with the uric acid forming urates which are freely soluble. He advises the administration of a flavored 12-grain sodium chloride tablet. The patient places on the tongue a half tablet and drinks a glassful of water (better hot) before each meal, and in the middle of the forenoon (10 A. M.), middle of the afternoon (3 P. M.), and at bedtime (9 P. M.). The patient thus drinks three pints of (¼ to ½) decinormal salt solution daily. This practically renders the urine normal, and acts as ample prophylaxis against the formation of uric acid calculus. If parenchymatous nephritis exists the sodium chloride should not be administered, as it excessively stimulates the renal parenchymatous cells. In such cases the water only should be given. An alkaline tablet is also given. It is composed of: cascara sagrada, 1.6 mg. (1-40 gr.); aloes, .022 gm. (1-3 gr.); sodium bicarbonate, .065 gm. (1 gr.); potassium bicarbonate, .022 gm. (1-3 gr.); magnesium sulphate, .13 gm. (2 gr.). One-sixth to one tablet (or more as required to move the bowels once daily) is placed on the tongue before meals and followed by 236 c.c. (8 oz.) of water (better hot). At 10 A. M., 3 P. M., and bedtime one-sixth of one tablet is placed on the tongue and followed by a glassful of fluid. In the combined treatment the sodium chloride tablet and alkaline tablet are both placed on the tongue together. This method furnishes alkaline bases (sodium and potassium) to combine with the free uric acid, in the urine, producing perfectly soluble alkaline urates and materially diminishing the free uric acid. The alkaline and sodium chloride tablets take the place of all so-called mineral waters.

*Journal of the American Medical Association, August 26, 1905.*

**The Elimination of Mosquitos.**—A. H. Doty describes the habits of the mosquitos, so far as they are known, with special reference to the extermination of the insect. The first important fact is that mosquitos propagate only in water, and the commonest form, the culex, has a special preference for contaminated or foul waters. There is a salt-water mosquito which abounds on the Atlantic coast and breeds in the salt marshes, hibernating in the mud when they are not overflowed. The common impression that the mosquito is a short-lived insect is not altogether correct, and Doty thinks that a large proportion of the earlier mosquitos of the season are insects that have hibernated during the winter. They can live for many weeks during the warm weather, and have been kept for weeks in captivity. The anopheles or malaria-bearing mosquito differs from culex in not preferring contaminated waters, but breeds rather in surface water with green scum. It may be found together with the culex in offensive water, but this is rare. As a rule, mosquitos do not go far from home, though they may be carried by the winds or public conveyances. In localities where they abound their breeding place is generally at no great distance. These breeding places are sometimes in the most unexpected locations, and he gives an instance of malaria traced to an old cakepan, nearly buried in long grass, which abounded in anopheles. The prevention of the propagation of mosquitos consists in abolishing or removing the water receptacles in which they breed, by drainage, filling, covering, and screening cisterns, and the use of petroleum oil as a temporary measure, when these other measures cannot at once be carried out. The oil is cheap, practically harmless, and destroys the larvæ. Chemicals, besides being possibly dangerous, are comparatively ineffective. All mosquitos are most active after sundown. In the daytime they live in the high grass and underbrush, and in mosquito-infected districts this should be removed.

**Summer Diarrhea.**—M. Ostheimer discusses the methods of prevention of infantile summer diarrhea. The most important thing, he states, is to educate parents to keep children properly bathed, to keep them cool, to remove soiled napkins, to see that the children obtain sufficient sleep, to protect them from infection by flies, and to regulate their diet. Frequency of feeding, cleansing of bottles, etc., must all be taught. With the appearance of any gastrointestinal disturbance, the milk should be stopped and barley water or whey given. This education of the parents is best accomplished by the judicous distribution of pamphlets, instructing mothers in the care of infants during the heated term. In the fifteen largest cities of the country such distribution is provided for only in nine, and details are given as to the extent of this useful practice. It would be advisable, Ostheimer thinks, to have special "milk" courses given in the public schools, the high schools, especially, and in the medical schools and hospitals. The fact that clean milk can be procured will then be recognized. It would be well also if large cities would run a dairy under the supervision of the health department. If this is impracticable, such a dairy could be established by private subscription. Ostheimer gives a sample of instructions to be issued by health departments, based on the pamphlets already mentioned, to be given out by district physicians and medical inspectors, and also to be distributed from dispensaries, milk depots, etc. Some should also be given to physicians in general practice for the benefit of patients, the well-to-do as well as the poor.

**Summer Diarrhea.**—J. C. Cook reports the results of bacteriological and blood examinations in fifteen infants suffering apparently from summer diarrhea during the months of July and August, 1904. In eleven non-fatal cases, averaging nine and one-third months, in which the children had been carelessly fed by poorly nourished and ignorant mothers, the most striking bacteriological findings were the frequency of the pneumococcus, this microorganism being found in seven cases each of examinations of the stools and the throat. The colon bacillus was found in the stools in seven and in the throat in six cases. The bowel movements were not excessively frequent, averaging four daily in these milder cases. In one of the fatal cases, well-marked bronchopneumonia existed and the pneumococcus was present in every organ examined, as well as in the blood and stools. The same complication was present in another of the four fatal cases, and the pneumococcus was found in the stools as well as in the lungs. In another fatal case there was found a red pigmenting bacillus of the colon group staining the stools blood red and causing the attending nurse to report hemorrhage, though microscopic examination revealed no evidence of it. Cook remarks that in some cases of infantile diarrhea a septic condition is probably set up by the entrance into the system, through the bowel lesions, of well-known pathogenic germs like the pneumomococcus, and that this specific intoxication may be masked by the symptom of the milder infection.

**Iodine as a Germicide.**—The results of an elaborate study of the antimicrobic action of iodine are published by Guy C. Kinnaman. The tests were made with solutions of different strength, tested as to their asepticity, and applied to growths on solid media, so as to approach as nearly as possible to the actual relations of bacteria to the body in disease. Thus, by the thickness of the growth, the penetration and germicide action of the liquid could be ascertained. The microorganisms tested were: (1) Bacillus prodigiosus; (2) Bacillus anthracis and spores; (3) Bacillus tuberculosis; (4) Staphylococcus pyogenes aureus; (5) Streptococcus pyogenes; (6) Blastomyces dermatidis; and (7) Actinomyces bovis. The method of making the tests and controls is described, with details of the experiments with each species, and the results are discussed. The conclusions reached are summarized in substance as follows: in a solution of iodine, varying from 0.2 to 1 per cent., we have a very potent germicidal agent, far superior to bichloride of mercury, the acknowledged leader of all other antiseptics. It approaches nearly to the ideal antiseptic in that: (*a*) It is easily prepared and is stable; (*b*) it is nontoxic and nonirritating in strength effective, being only one-fourth as toxic as bichloride of mercury; (*c*) it does not coagulate albumin or form inert compounds with tissues; (*d*) it is effective in a very brief time; (*e*) the stain it produces soon disappears; (*f*) last and most important, it possesses a remarkable penetrating power. In conclusion, he remarks that an 0.5 per cent. solution is amply strong enough for all practical purposes.

**Dynamic (Spastic) Astigmatism.**—This is defined by F. B. Eaton as a condition of the eye due to dynamic changes in its media which prevent homocentric rays from being brought to a focus on the retina. While its occurrence is questioned by some authorities, there is a predominance of opinion in its favor, and Eaton, besides quoting from others, gives the results of subjective and objective investigations of his own and of others' eyes, which, he says, apparently prove that dynamic astigmatism is caused by the accommodative apparatus on the one hand and by the extraocular muscles on the other. He thinks the condition exists very frequently, and nearly always in tired, irritable eyes affected with organic (corneal or lenticular) astigmatism. It is often overlooked because it is thought that the ciliary muscle and the convergence excess have been completely paralyzed by some weak or strong cycloplegic. While it usually disappears at the presbyopic age, there are exceptions. Eaton has seen it once in a woman aged seventy-three. While its mechanism is not easy to explain, Eaton is inclined to believe, as a result of his studies, that both the accommodative apparatus and the extraocular muscles may have a part in its production. He insists on its practical clinical importance, and pleads for caution in estimating the total refractive error in many cases "until time, cycloplegic's rest, aided, if necessary, by the hypodermic use of hyoscin hydrobromate and bromids or other sedatives, with patient 'fogging' at times, has eliminated all dynamic contractions." The condition, he says, is frequent, and failure to recognize it often accounts for the discrepancies in the refractive findings of competent ophthalmologists.

*The Lancet, August* 19, 1905.

**Subdiaphragmatic Transperitoneal Massage of the Heart as a Means of Resuscitation.**—H. M. W. Gray reports the case of a female aged fifty-five years, who suffered for three months with increasing dyspnea from laryngeal obstruction, so severe as to necessitate her removal to the hospital. On admission she was deeply cyanosed and expiration was much interfered with. No intralaryngeal examination was made. Soon after admission he was informed that the patient was dying, and he found her making a feeble, choky inspiratory effort. High tracheotomy was at once performed and artificial respiration proceeded with. There was no pulse at the wrist nor any cardiac impulse. No cardiac sounds could be heard. All reflexes had disappeared, the pupils were widely dilated, the muscles flaccid, and the eyes assumed the "glassy" look. Various methods of resuscitation were attempted but were unavailing. Four or five minutes after the tracheotomy was done the abdomen was opened and the outlines of the heart were easily palpated with the two fingers; it was absolutely flaccid. Massage by intermittent pressure was carried on at the rate of 70 to 90 per minute, and at the end of 15 to 30 seconds he felt the heart muscle becoming firm. After remaining thus for a few minutes a slight tremor was felt. Then very slowly the heart began to beat, at first very feebly. He massaged the heart for a few seconds more and then it beat gradually more strongly and quickly until at last it beat at the rate of 90 and more vigorously than on admission. Very soon after the heart began to beat the patient took a rather deep

spontaneous breath and gradually respiration became normal. Two hours after the tracheotomy the patient, much to his surprise, died, having never regained consciousness. The cause of the laryngeal obstruction was a fairly large cancerous growth. Probably ten minutes elapsed between the times the heart stopped beating and when it began again.

**The Presence of Pigment Containing Iron in the Thyroid Gland.**—G. Lovell Gulland and Alexander Goodall make a preliminary report on this and summarize their findings as follows: (1) In cases of diseases of the blood and in animals injected with phenylhydrazin we found pigment in the thyroid gland. The greater part of the pigment gives the iron free reaction. (2) The pigment is most commonly found in connective tissue cells between the vesicles. It is also present in small scattered areas in the epithelium lining the vesicles and may be found in cells lying free among the colloid material. (3) It is most abundant in the more cellular parts of the thyroid where the colloid vesicles are small.

**A Case of Mixed-Celled Leukemia, with a Short Account of Recent Views on Atypical Leukemias.**—Carl Hamilton Browning says that: (1) Myeloid leukemia is due to a hyperplasia of myeloid tissue; but the unknown causative agent is irregular in its action, so that any of the various granular types may predominate or a mixed-cell blood picture may result from the reversion of many of the cells to the condition of the non-granular undifferentiated leucoblast or from the hyperplasia of such non-granular cells normally present in the marrow in small numbers. These undifferentiated leucoblasts may assume their embryonic activity and secrete granules. (2) In leukemias a mixed-cell blood picture may be due to: (*a*) a reversion of myeloid cells to the embryonic non-granular type; and (*b*) a reaction or mechanical disturbance of myeloid tissue owing to lymphoid hyperplasia with as a result the passage of myelocytes into the circulation. (3) It is to be understood that it is left quite an open question as to whether or not myeloid and lymphoid tissue may be concomitantly affected in a way similar to what occurs in myeloid and lymphoid leukemias respectively. If such occurred then we should have a mixed leukemia in the strict sense.

**The Staining Reactions of the Spirochætæ Found in Syphilitic Lesions.**—Leonard S. Dudgeon brings forward the results he has recently obtained by employing a slight modification in the strength and method of using Leishman's stain. A number of cover slip preparations were made from the exudate from a condyloma and these were stained as follows: (1) A few drops of a 1 per cent. solution of Leishman's powder (Grübler) in absolute methylic alcohol (Kahlbaum's) were poured on to the surface of the film preparation, just sufficient to cover completely the whole of the cover-slip. This was allowed to fix the specimen and to stain it for 30 minutes. (2) Double the volume of distilled water as to stain was now run on to the surface of the cover-slip and the stain and water were carefully mixed. The staining was further continued for five minutes. (3) The diluted stain was poured off and distilled water was run on the cover-slip and allowed to remain on for one minute. (4) Surplus stain and any precipitate were now removed by squirting some distilled water on to the film from a pipette. (5) The film was then dried with cigarette paper and mounted in Canada balsam. Excellent preparations of the organism were obtained by this process and he was able to observe a large number of spirochætæ in most of the film preparations. Its morphological characteristics corresponded to the type described by Schadinn and Hoffmann as the *Spirochæta pallida*. It was found to be extremely delicate, but perhaps the most noticeable point concerning this organism was the typical corkscrew arrangement; in some cases from ten to fifteen turns were seen. Each spiral was sharply defined.

*British Medical Journal, August 19, 1905.*

**On the Care of Soldiers' Feet.**—G. S. Crawford says that one of the principal points to be attended to in examining new recruits is to see that their feet are well formed. He gives some suggestions as to the best way of keeping the feet in good order. Boots should be fitted indoors over thick socks, lacing them and testing their comfort in walking. They should be large enough to allow for expansion in hot weather and should never have pointed toes. The heels should be broad and low, soles thick but pliant, the vamp roomy over the toes, as pressure on the toes must be prevented. They should fit comfortably over the instep. Socks should fit comfortably after three washings, and should be of wool, with no irritating dyes. They must be smoothly darned, and washed clean. Canvas shoes rest the feet after a long march. The feet should be frequently washed, and if tender, soaked at night in alum or soft water, and rubbed in the morning with zinc or boracic acid ointment. The author suggests treatment for the common ailments. The common causes of swelling and inflammation are seams, wrinkles or projections in the socks, grit in the boots, lack of cleanliness. Sweaty feet may be relieved by cleanliness, boracic acid or zinc powder in the socks, and rubbing with belladonna ointment. Blisters are caused by pressure. If not yet raised, protection of the surface by a piece of plaster soaked in hot water, with a hole cut out the size of the blister will prevent the blister from filling. Over this is put a larger square piece with corners cut off. If the blister is raised, draw off the fluid with a clean surgical needle, entered one-eighth of an inch from the edge of the blister, in the sound skin, and passed horizontally. Flatten the blister and apply a pad and bandage. Hard corns should be carefully pared and pressure prevented. Soft corns should be treated by wearing cotton between the toes to soak up perspiration, when they become hard and may be pared. Lead and opium wash is the best application for inflamed corns. Chilblains arise from sitting by the fire with cold wet socks and boots on. A tendency to chilblains is rendered by keeping the feet dry. rubbing with a stimulating liniment and wearing thin socks. The toe nails should be cut square. Slight cases of ingrowing nail are cured by removing pressure, and pressing a wick of cotton under the corners of the nails.

**Temperatures During the Puerperium.**—John W. Duncan found a subnormal temperature daily in the axilla in sixty consecutive cases during the puerperium. Eight cases showed a temperature of 100° or over. These cases were under strict antiseptic precautions. The highest temperature, of 103°, was due to tense breasts, complicated with tinea of the breasts. The daily average mouth temperature was 99.3° on the third day, on the fourth 99.5°. Temperature above normal is due to faulty cleanliness, external skin infection, infection before labor, as in vaginitis, and small tears early in labor. Instrumental delivery does not cause rise of temperature as a rule. The author believes that infections come more often from the skin, cervical or vaginal mucous membranes or pudindol surfaces of the patient than from the doctor and nurse.

**A Case of Quinine Amblyopia.**—G. Victor Metler details a case of amblyopia due to the taking of quinine in 5-grain doses three times a day for several weeks. The vision was 5-15, and he was unable to read or write. The retinal vessels were very small, the optic discs pale, and outline hazy. He used a great deal of tobacco. This and the quinine were stopped, and nitroglycerine given. Recovery was complete.

**Measles.**—Hugh M. Raven observed an epidemic of measles among schoolboys, one of whom was said to have had the disease as a child. This one developed, at the same time that the others had the rash, an ulcerative tonsillitis, complicated with nephritis, probably due to the poison of measles acting on the kidney. The glands at the angle of the jaw were much enlarged; the urine contained much blood, epithelial and granular casts. Conjunctivitis and postnasal catarrh and bronchitis were present, but no eruption. The amount of urine was 30 to 60 ounces per day; specific gravity, 1.010. The urine was not normal until the eighth week.

*Berliner klinische Wochenschrift, August 7, 1905.*

**Governmental Supervision in the Control of Trachoma.**—Greeff calls attention to the prevalence of trachoma in some districts of Germany as opposed to its relative rarity in other sections. Improvement in the supply of water with resulting increase of cleanliness, but, above all, the efforts of competent physicians in control of the dispensaries, working with the support of the government, thus enabling them to receive and treat poor patients—these are the factors to which Greeff ascribes the disappearance of trachoma from districts in which it was formerly one of the most widespread of contagious diseases. Prophylaxis is especially important, since cases rarely remain under treatment long enough to effect a complete cure, and therefore remain for years a dangerous source of infection.

*Münchener medizinische Wochenschrift, August 8, 1905.*

**A New Hemometer.**—Grützner has elaborated an instrument for the determination of hemoglobin for which he claims both simplicity and accuracy. The apparatus consists of a wedge-shaped glass receptacle with glass-lined metal sides varying from 3 mm. in depth at the rounded apex to 15 mm. at the base. Into this wedge a small amount of blood diluted with water is poured from a glass mixing chamber. This dilution is effected by means of two pipettes, one for water, the other for blood, so graduated that an exact dilution of 1:100 is obtained. As a standard the author has selected a layer of normal blood of this dilution 5 mm. thick. This standard corresponds to 100 per cent. Hb. A strip of clay stained with pierocarmin to correspond to this color is attached to the wedge to serve as a standard for comparison. A sliding metal sheet perforated with three horizontal openings each 1 mm. wide is fitted over the front of the wedge and of the colored stand-

ard. This sheet is now raised or lowered until the middle band coincides in color with the standard. The upper band will then be darker, the lower band lighter than the standard. From the thickness of the layer of blood at this point the amount of Hb. can be determined from tables supplied with the instrument. To avoid errors caused by oblique illumination the readings should be made through the black paper tube that accompanies the apparatus, and can be accurately adjusted to the wedge.

**The Relation of Leucocytes to Erythrocytes in the Treatment of Leukemia with Röntgen Rays.**—Arneth has carefully followed the blood changes in cases of leukemia under treatment with *x*-rays, and comes to the following conclusions: The number of leucocytes constantly diminishes until in some cases, at least, the norm is reached. Simultaneously there is an increase in the number of erythrocytes, but this increase is relatively slower. The hemoglobin also increases, but not in proportion to the increase in the number of red blood cells. The color index never reaches the normal point. The erythrocytes reach their maximum some time after the leucocytes have become normal in number, and may even continue to increase when a recurrence, with increase of leucocytes, has already begun. In such cases there is a subsequent decrease in the number of erythrocytes, and a still more rapid fall in the amount of hemoglobin. With the increase of red blood cells normoblasts disappear from the circulation, only to reappear as the blood again assumes its leukemic character. Their reappearance occurs even before the blood has reached the point at which they were no longer found in the circulation. Other changes in the blood will be discussed in a later paper.

**The Perviousness of the Gastrointestinal Tract of Newborn Animals to Bacteria and to Albumins.**—Uffenheimer concludes from his experiments in feeding newborn guinea-pigs with cultures of micrococcus tetragenes, anthrax, bacillus prodigiosus, and tubercle bacilli, that the intestinal mucosa does not permit the passage of bacteria through it into the blood and tissues. An exception is offered in the case of the tubercle bacillus. With this organism positive results were obtained in every experiment both with young and with old animals, the latter, however, requiring a larger dose of the culture. The passage of the bacilli is effected through an intact mucosa. Tuberculous lesions of the intestine the author ascribes to retrograde infection from the mesenteric lymph nodes. Infection proceeded either from the mouth or from the gastrointestinal tract, most often from the appendix vermiformis. Inoculation of a second series of animals with gland substance and blood obtained from animals fed with tubercle bacilli a short time after the feeding was followed by the formation of non-tuberculous nodules in the lungs of the inoculated animals. Neither specific hemolytic serum nor casein from cows' milk is absorbed in newborn guinea-pigs. Slight amounts of egg albumen were occasionally absorbed into the blood, but no antibodies were formed. With diphtheria and tetanus antitoxin small amounts were constantly found in the blood of young animals, but none was absorbed by older animals. Control experiments with newborn rabbits fed with bacillus prodigiosus and with egg albumen gave uniform positive results. Histologically the gastrointestinal mucosa of the newborn guinea-pig differs in no way from that of the adult animal.

**The Influence of Red Rays on Scarlet Fever.**—Cnopf finds that the exposure of scarlet fever patients to red light and the exclusion of all other rays results in a prompt diminution in the intensity of the cutaneous eruption, and in an early fall of temperature, usually by crisis, on the fourth to sixth day. A lytic defervescence is occasionally seen. Recrudescences in temperature usually denote some complication. The paling of the skin is not indicative of a subsidence of the dermatitis, the skin again becoming red on exposure to ordinary light.

*Deutsche medizinische Wochenschrift, August* 10, 1905.

**A New and Active Constituent of Ergot.**—Vahlen has isolated from Secale cornutum a non-toxic principle to which he assigns the name clavin. This substance exerts a specific action in stimulating the contractions of the uterus. It causes neither gangrene like sphacelinic acid nor tonic convulsions like cornutin, the other active principles of ergot heretofore known. Clavin is soluble in water and can be obtained from its aqueous solution by evaporation in the form of a microcrystalline powder. From a warm concentrated alcoholic solution it is thrown down in the form of prismatic crystals 7 to 8 mm. long, that can be sublimated by careful heating. Clavin is insoluble in cold alcohol, ether, and acetic ether. Its empirical formula is $C_{11}\ H_{22}\ N_2\ O_4$. It does not form salts. Intravenous injection of several decigrammes in dogs and cats was followed by no toxic symptoms, while a far smaller dose exerted a marked action upon the uterus, especially in gravid animals. The writer cites two cases of protracted labor in the human female in which the subcutaneous injection of 0.01-0.02 gm. of clavin in a 2 per cent. aqueous solution was promptly followed by increase in the number and duration of labor pains, and by rapid delivery. No local irritation follows this method of administration.

**The Treatment of Mammary Tumors in the Female.**—Braatz emphasizes the necessity for early removal of all tumors of the mamma, on the ground that malignant degeneration in a benign tumor is by no means uncommon. Encapsulated benign tumors may be removed under local anesthesia of the skin alone by the Schleich infiltration method. Enucleation is effected by cutting with scissors towards the capsule of the tumor. No pain is experienced unless the surrounding breast tissue itself is incised. Malignant tumors should always be removed under general anesthesia, as the large amount of fluid used in the Schleich method not alone obscures the limits of the tumor, but may also force tumor cells into the lymph spaces through the increase of pressure in the tissues. To secure the best possible exposure of the axilla Braatz recommends an incision extending from the middle of the sternum to the posterior axillary fold about 5 cm. below the apex of the axilla. This is joined by a vertical incision beginning at the junction of the outer and middle thirds of the clavicle. The external triangular flap thus formed is dissected back to expose the attachments of the pectorales major and minor to the humerus and coracoid processes respectively. These attachments are cut through, exposing fully the axillary vein. The axillary lymph nodes are now dissected out. A third incision is made curving below the breast, and uniting the ends of the first incision. Breast, pectoral muscles, and axillary contents are now removed together. The skin flaps are best approximated by passing a double ligature through the lower edge of the wound opposite the end of the vertical incision, either ligature being then continued through one of the apices of the upper flaps. The ligatures are united laterally as well as from above downward. The remainder of the wound is closed with interrupted sutures. Its most dependent part is drained with a split tube drain passing through a buttonhole in the skin. Motion of the arms is unimpaired since this operation leaves no scar in the axilla to interfere with extension through contraction.

**The Pathogenic Significance of Bacillus Funduliformis.**—Kisskalt isolated this organism from pus obtained from a pelvic abscess incised through the abdominal wall. Incision and irrigation with hydrogen peroxide were followed by prompt recovery. The organism is a non-motile, polymorphous streptobacillus. It is stained with difficulty with the ordinary dyes, not at all with Gram's stain. The best results are obtained with dilute borax-methylene blue and with dilute carbolfuchsin. The bacillus is an obligatory aërobe. It grows upon all the ordinary media, but poorly in the absence of albumin. Gas is formed in the presence of glucose, lactose, and saccharose. Milk is not coagulated, nor is gelatine fluidified. Indol is formed abundantly in older cultures. No spores are present, but in the first generation many bacilli showed a distinct thickening at the center. The bacillus is non-pathogenic for mice, guinea-pigs, and pigeons. Subcutaneous injections of a pure culture into rabbits gave inconstant results. Where these were positive, a localized emphysema of the tissues developed after twenty-four hours, gradually increasing in extent. Later an abscess formed from which the bacilli could be recovered in pure culture. The infected animals recovered spontaneously. Agglutination experiments were negative. The author believes the determination of the presence of anerobic bacilli in infections of importance, since disinfection with hydrogen dioxid will probably in such cases aid materially in the destruction of the invading organism.

*French and Italian Journals.*

**Prophylaxis of Epidemic Cerebrospinal Meningitis.**—M. Vergote gives us the results of the consultation of the Council appointed to decide what measures were necessary to prevent the entrance of epidemic cerebrospinal meningitis into Belgium. From the point of view of its contagiousness, cerebrospinal meningitis is not to be compared with such diseases as smallpox. Local conditions, at present unknown, and a peculiar individual susceptibility have much to do with the passage of the disease from one person to another. Propagation from one person to another in a family is so rare that direct transmission seems doubtful. Where it appears we find conditions of overcrowding, yet rarely is there more than one patient in the same family. Schools and barracks have been spared. The present appearance has been rather sporadic than epidemic, the cases being isolated. Its transmission is limited to the immediate neighborhood and to direct contact. The fact that it has occurred so sparingly is due to the lack of individual receptivity in the persons exposed. Hence, the ordinary measures used in the common contagious diseases are sufficient.

and no new and more severe measures are necessary to prevent its spread.—*Le Mouvement Hygiénique*, June, 1905.

**Treatment of Nurselings of Retarded Development.**—Eugene Terrion considers as retarded in development any child at birth weighing less than 2,500 grammes. The principal cause of such lack of development is premature birth. It may result also from improper feeding and alimentary disorders. Absorption is difficult, assimilation is poor, the entire digestive tube is badly developed. If milk is given in sufficient amount it is rejected. The amount given should be reduced, and the time of feeding brought nearer together. Mother's milk is the only desirable food; cow's milk is not digested. When mother's milk cannot be taken, pepsin may be given with it. A sort of mixed feeding is sometimes necessary, consisting of bouillon of vegetables, with a small amount of cream of rice, and this may be tolerated when milk is rejected. Before the tenth day the amount of milk is regulated by the weight of the child; after that time it should be equal to, or a little more than a fifth of his weight. The food should be given in small quantities and at short intervals. As the alimentary troubles lessen the amount of food is increased. These children must be kept very warm.—*La Presse Médicale*, July 22, 1905.

**The Genital Crisis in the Newborn.**—R. Romme calls attention to what he considers to be a genital crisis, arising soon after birth, in the newborn. The changes in the skin which belong to the formation of the vernix caseosa and fetal acne are the signs of an infantile puberty. The phenomena of puberty are all due to the establishment of the internal secretions of the ovaries and testicles. All these phenomena are imitated to a less degree in the first weeks of life. There is sometimes observed in little girls, about the sixth or seventh day, a true hemorrhage from the genital passages, corresponding to the menstrual discharge. It is variable in amount, but sufficient to form a drop on the labia. It lasts no longer than thirty-six to forty hours. It occurs in 35 per cent. of all cases. When this does not occur, if the vaginal secretions are examined, red blood corpuscles will be found. It is the result of modifications going on in the uterus. The uterus diminishes in size during the first week of life, and decreases up to two years of age. When this early hemorrhage occurs there is a marked congestion of the uterus, and subepithelial hemorrhages take place. Some believe that there is no congestion of the ovaries, while it is stated by others that the Graafian follicles are already formed. A similar phenomenon occurs in the testicles of the boy, a passing congestion. The prostate is congested, increased in volume, the glandular epithelium filling the canals of secretion. Hydrocele that is soon absorbed is quite frequent, due to changes in the testicles. On the sixth to eighth day after birth both sexes have a congestion of the mammary gland, with secretion of creamy fluid; this occurs in forty-one out of one hundred cases. It is produced by proliferation of the epithelial elements, and their transformation into a milky fluid. Involution goes on naturally until the gland returns to the natural size. The vernix caseosa and miliary seborrhea of the newborn also belong to this crisis, as well as fetal acne. There are two theories as to this crisis; Jacquet tells us that this is the close of the development of the genital organs, which begins at the fourth month, and ends at birth. Halban refers it to the internal secretion of the placenta acting on the fetus in the womb, and ceasing at birth. This is the process of involution following its action.—*La Presse Médicale*, July 19, 1905.

**Puerperal Pyemia the Result of the Staphylococcus Alone.**—J. Schwetz publishes a case of puerperal pyemia resulting from a pure culture of staphylococcus, because this is a form of pyemia that is quite rare. We now know that puerperal pyemia is produced by other microbes, namely, streptycoccus pyogenes, staphylococcus pyogenes albus and aureus, pneumococcus, gonococcus, bacterium coli, and the septic vibrio of Pasteur. Those produced by the other microbes are always associated with the streptococcus. This case was observed at the maternity at Lausanne, was followed by an autopsy and a complete bacteriological examination. It occurred after a four months' miscarriage, in a woman who had had three normal labors. Curettage was done to remove the secundines, and intrauterine injections given, as well as injections of antistreptococcic serum, but without effect. At the autopsy it was found that there were thrombi in the right spermatic and uteroovarian veins, and abscesses in the right ovary and parametrium. The bacteriological examination showed only staphylococcus aureus. Only eleven cases of this variety of infection in puerperal patients have been reported. The author believes that during life we cannot diagnose between a pyemia due to staphylococci and that due to streptococci by the clinical symptoms; only a bacterial examination can decide this. The streptococcus infections are in general more severe. Of the cases due to the staphylococcus that have been reported, only two have recovered. It is rather the virulence than the kind of germ that is important. The gonococcus infections are also serious. The treatment of a case of puerperal fever with antistreptococcic serum would be useless, if the infection were produced by the staphylococcus. Hence bacteriological examination becomes of value in directing the kind of serum to be used. Curettage is also useless when the infection has passed from the mucous membrane of the uterus into the veins and become general.—*Annales de Gynécologie et d'Obstetrique*, July, 1905.

**Etiology and Pathogenesis of Acute Pemphigus in Babies.**—Olympio Cozzoline tells us that, although acute pemphigus is frequent in young babies, it is by no means confined to them, occurring in children of all ages. Its rarity in infants after the early weeks is due to their lessened susceptibility to the disease, and their relative isolation from the sources of contagion. The source of contagion is often found in the birth of the children in maternity institutions, which are frequently affected by epidemics. When the child is taken home to live, he is less liable to come in contact with other cases. All the other members of a family may be affected from the infant who has the trouble. In adults with normal skins we never see a diffuse bullous eruption, but only a few spots, especially around the breasts and in the axillæ, where the child puts his hands in nursing. It is asserted that the disease is quite common in the tropics, diffused over the entire body. The author has made bacteriological examinations of the blood in a case contracted by the baby from his brother. They were completely negative. He made cultures of the blood, and found two colonies of staphylococcus aureus. He tested the agglutinating power of the blood of this baby, the serum diagnosis was positive in dilutions of 1-100. From his brother he got the agglutination positive at 1-40. His conclusions are as follows: (1 Pemphigus acutus is a general, febrile affection, of eruptive type, not a simple skin disease. It is contagious, and inoculable at all ages. (2) The location of bullæ on the soles of the feet is not peculiar to syphilis. The cause is probably the staphylococcus aureus.—*Rivista di Clinica Pediatrica*, July, 1905.

**Secretory Activity of the Thyroid in Some Morbid Conditions.**—N. Tiberti believes that a minute histological study of the organs of internal secretion will contribute to throw light on the complex question of their function. He has studied the secretions of the thyroid in animals after ligation of the ductus choledocus, suppression of the renal functions by bilateral nephrectomy, occlusion of the intestine, in experimental diabetes, and in the human subject in cases of cystic and parenchymatous goiter. There are two secretions of the thyroid glands, a colloid substance and a series of granules found in the cells, especially in the portion near the lumen of the vesicles. These begin to be produced as soon as the gland begins to functionate. The author believes that his experiments tend to confirm the theory of the antitoxic function of the thyroid. His conclusions are as follows: In grave cases of autointoxication the granular secretion is modified, both in the number and the size of the granules. The increase is greatest in uremic poisoning, and present in icterus and intestinal occlusion. In diabetes it is diminished, while the colloid substance is increased. In tetanus the secretion is increased. In cystic gotier the granules are diminished in proportion to the atrophy of the gland. In parenchymatous goiter it is increased, especially in the new-formed alveoli.—*Lo Sperimentale*, Vol. III-IV, Anno LIX.

**Serious Puerperal Anemia.**—I. Clivio details his observations of twenty-five cases of grave anemia in pregnancy seen at the hospital at Parma. They were taken from a region where anemia is frequent, but the degree was much more severe than in men, or in non-pregnant women. Several of the cases were so severe that they responded to no treatment, and a fatal issue resulted. The author's conclusions are as follows: (1) Pregnancy has a marked influence on anemia of a certain degree, and simple anemia is changed to the pernicious form. This is probably due to the feto-placental changes, and is much increased in the last three months. (2) There is a condition of lessened resistance to putrefactive changes, both of intestinal and placental origin, and intestinal complications are serious and fatal. (3) The increase in the volume of the spleen, which has been observed in all severe cases, is the expression of increased activity in the destruction of the incomplete red blood corpuscles that have been formed. (4) The treatment should be both obstetrical, by induction of premature labor, and medical. (5) Labor is easy and rapid in this condition. (6) In severe puerperal anemia the use of red bone-marrow is of the greatest value, especially after pregnancy has been interrupted.—*Annali di Ostetricia e Ginecologia*, June, 1905.

# Book Reviews.

A Manual of Midwifery, for Students and Practitioners. By Henry Jellett, B.A., M.D. (Dub. Univ.), F.R.C.P.I., L.M., Gynecologist and Obstetric Physician to Dr. Steevens' Hospital, Dublin; Extern Examiner in Midwifery, Royal University of Ireland; Examiner in Midwifery, Royal College of Physicians, Ireland; Ex-Assistant Master, Rotunda Hospital; Ex-University Examiner in Midwifery and Gynecology, Dublin University. With the assistance in special subjects of W. R. Dawson, M.D., F.R.C.P.I., Medical Superintendent, Farnham House, Dublin; Examiner in Forensic Medicine, Royal College of Physicians, Ireland; H. C. Drury, M.D., F.R.C.P.I., Physician to Sir Patrick Dun's Hospital, and to Cork Street Fever Hospital, Dublin; T. G. Moorhead, M.D., Physician to the Royal City of Dublin Hospital, Demonstrator in Anatomy, School of Physic, Trinity College, Dublin; R. J. Rowlette, M.D., Pathologist to the Rotunda Hospital, and to Dr. Steevens' Hospital, Dublin; Lecturer on Pathology, Queen's College, Galway. With Nine Plates and 467 Illustrations in the Text. New York: William Wood and Company, 1905.

In this volume the reader will find a complete account of the theory and practice of modern obstetrics. The first part of the book deals with obstetrical anatomy, both maternal and ovular. This is followed by chapters on obstetrical asepsis and antisepsis, the obstetrical armamentarium, and obstetrical diagnosis. The physiology of pregnancy, labor, and the puerperium are next considered. The succeeding parts discuss in considerable detail the various questions concerning the pathology of pregnancy, labor, and the puerperium. This is much the largest and most important part of the work, and the reader will find here an adequate presentation and solution of the many difficulties which beset this branch of the subject. There is a section on obstetrical operations; and the last part consists of two chapters on the infant.

While there is little new in this volume (and one neither looks for nor welcomes the merely new), old views are presented in a new light, and everything is discussed in a pleasant and lively style. Among the chapters which have particularly interested us may be mentioned those on the bacteriology of the genital tract, extrauterine pregnancy, and the hemorrhages, both antepartum and postpartum. The author's wide experience and grasp of the subject are apparent in every chapter; and throughout, the reader feels that he can not only rely on every statement made, but can also with safety and confidence consult the volume when in need of information.

The New Knowledge. A Popular Account of the New Physics and the New Chemistry in Their Relation to the New Theory of Matter. By Robert Kennedy Duncan, Professor of Chemistry in Washington and Jefferson College. New York: A. S. Barnes & Company, 1905.

This is a fascinatingly interesting book, holding the reader's attention from first page to last, and holding it in spite of the fact that to understand it attention must be directed most fixedly to the subject matter. The ordinary layman, who is not a specialist in any given science, seldom has the time to keep abreast of its advances by studying the technical treatises, nor can he always get satisfaction from the popular and sketchy magazine articles, yet, as one in the world who would not be absolutely ignorant of any of the wonderful things about him, he must have some source of authoritative information. Such a source of information he will find in Professor Duncan's book, so far as regards the nature and properties of matter as explained by the new chemistry and the new physics. The author begins with the atom, which as boys we were taught to believe was the smallest divisible particle of matter, but which we now learn is made up of hundreds or thousands of almost infinitely smaller corpuscles. It is the discovery of these corpuscles which has opened up a new and vast unknown country, of which we have as yet seen only the boundaries. Radioactivity, the nature of electricity, creation, life, the cause of the sun's heat, the destruction and the recreation of worlds, disease—the solution of these and a thousand other mysteries may or may not lie concealed in this new field which science is beginning to explore, but that a solution or explanation of some of them at least will be found here there can be no doubt. If one would be in position to understand these explanations when they are made, he must be conversant with the main facts and theories of this new knowledge, and it is the mission of this book to put him in possession of them. The book is not one to while away an idle hour or to be read in odd moments—it must be studied; but the wonders that a careful study of it will reveal will well repay one for the time spent and the attention given. So far as a difficult subject can be made lucid, the author has made it so—he has certainly presented it in a wonderfully interesting way.

Northnagel's Practice; Malaria, Influenza, and Dengue. By Dr. J. Mannaberg, of Vienna, and Dr. O. Leichtenstern, of Cologne. Edited, with Additions, by Ronald Ross, F.R.C.S., F.R.S., Professor of Tropical Medicine, University of Liverpool; J. W. W. Stephens, M.D., D.P.H., Walter Myers Lecturer in Tropical Medicine, University of Liverpool; and Albert S. Grünbaum, F.R.C.P., Professor of Experimental Medicine, University of Liverpool. Authorized Translation from the German, Under the Editorial Supervision of Alfred Stengel, M.D., Professor of Clinical Medicine in the University of Pennsylvania. Philadelphia and London: W. B. Saunders & Company, 1905.

As the article on malaria in this volume was written by Prof. Mannaberg at a time when the mosquito had not yet been dreamed of in the philosophy of the student of this disease, the duties of Dr. Stephens in remolding it from its original form into one nearer to present conceptions have been rather more extensive than those usually devolving upon the editors of productions of this sort. He has, however, performed his function of ringing out the old and ringing in the new with highly commendable tact, and though the discussion of the disease has perforce become a somewhat particolored mosaic, to the casual observer, at least, it presents a fairly homogeneous appearance. A section of over one hundred pages from his pen has been interpolated bodily, and forms what is perhaps the most interesting portion of the monograph, as it is devoted to the Hamlet of the play, the mosquito itself, and contains a wealth of information on the natural history of the Culicidæ, their relation to malaria, and the methods employed in studying the problems involved. The name of Major Ross, one of the pioneers in this work, appears on the title page of the book, but we have not been able to find any additions to the text accredited to his hand. The chapters on influenza and dengue by Prof. Leichtenstern have been revised by Dr. Grünbaum, who states that there has been but little addition to our knowledge of the former disease since the volume was first published, several years ago. He calls attention to the fact, however, that it should be remembered in reference to the remarks on the etiology of dengue, that it was written before the publication of Ross's researches on malaria and the discoveries which have arisen therefrom. An interesting table is included in this section, in which the differential diagnosis between influenza and dengue is made clear.

First Aid in Illness and Injury, Comprised in a Series of Chapters on The Human Machine, Its Structure, Its Implements of Repair, and the Accidents and Emergencies to Which It Is Liable. By James Evelyn Pilcher, M.D., L.H.D., Major and Brigade Surgeon of United States Volunteers; Captain in the Medical Department of the United States Army; Secretary and Editor of the Association of Military Surgeons of the United States. Ninth Edition. Revised, with 208 Illustrations. New York: Charles Scribner's Sons, 1905.

Although books dealing with the treatment of injuries are legion, this volume deserves a prominent place among them. Not only are injuries and their treatment discussed, but also "the construction of the human machine" and "the implements of repair." The first section includes the subjects: The skin, the fat, the bones, the joints, the muscles, the brain and nerves, the blood and its circulation, the larynx and the lungs, the stomach and bowels, the excretory apparatus, and the senses. One chapter is devoted to the emergencies of the battle-field. The last part of the book deals with such subjects as dwellings, disinfection, food, and infection.

Operative Surgery. By Joseph D. Bryant, M.D. Fourth Edition. New York: D. Appleton & Co., 1905.

This new edition of Bryant's classical work will be most gratefully received by the profession. Both volumes have been entirely revised, largely rewritten, and brought entirely up to date in every detail. The illustrations, of which there are about 1,800, many in color, are expressive and clear, and the subject matter is presented in the characteristic admirable style of the author. Both Dr. Bryant and his publishers are to be congratulated on this new edition, and we wish it the same success as was enjoyed by its predecessors.

Le Traitement de l'Hypertrophie Sénile de la Prostate. Par le Docteur A. Guépin, Chirurgien Chef du Service des Voies Urinaires à l'Hôpital Péan. Paris: Félix Alcan, 1905.

In this brochure Dr. Guépin reviews the three anatomicopathological phases and the three clinical stages of senile hypertrophy of the prostate, and indicates the hygiene, diet, and medication appropriate to each. The reader will find here formulæ, clinical reports, and enough of theory to justify the various methods of treatment advocated, and to serve as a basis for the selection of one or the other procedure as indicated in the individual case.

## AMERICAN LARYNGOLOGICAL ASSOCIATION.

*Twenty-Seventh Annual Meeting, Held in Atlantic City, June 1, 2 and 3, 1905.*

THE PRESIDENT, DR. CLARENCE C. RICE, IN THE CHAIR.

**President's Address.**—Dr. CLARENCE C. RICE, in his opening address, stated that it was the work of this association to study and understand the qualities of the mucous membrane, which were probably much more varied than was to-day suspected. It was their special province to determine what conditions of the nasal passages and of the throat were most favorable for the entrance of the many varieties of bacteria, not only for those germs which find their entrance through these channels, but for all diseases whose methods of attack were less thoroughly, or, perhaps, not at all, understood. It was his belief that many diseases might be stopped altogether if the method of entrance and the pathological peculiarities of the mucous membrane were better understood. Was there, for instance, a condition of the nasal passages by reason of which the germ of cerebrospinal meningitis found easy access into the organism? No association had greater responsibility in fighting the ravages of tuberculous infection than had the Laryngological Association. The well-being of the entire respiratory surface, which it was the duty of the members of this association to safeguard, meant in a large majority of cases comfortable protection against the attacks of innumerable varieties of infection. Dr. Rice suggested as a wise measure that there be a special committee empowered to arrange a schedule of work for the annual sessions which would cover all the burning questions of the day, and appoint commissions to investigate such vital subjects as the phases of tuberculous infection, malignant growths, the etiology of hay fever, etc., and that such committees should report at later meetings in order that the American Laryngological Association might place itself on record, and so keep fully abreast of progress in all scientific research.

**Partial Turbinectomy Followed by Acute Otitis, Mastoiditis, and Sigmoid Sinus Thrombosis, with Extension to Internal Jugular Vein.**—Drs. CHARLES H. KNIGHT, and JAMES F. MCKERNON of New York presented a paper with this title. The authors stated that one was apt to lose sight of the risks attending what are called "minor" operations until brought to realize them by rude shock, like that experienced in the case reported. It was quite possible that similar cases were not infrequent. In this connection reference was made to a paper presented to the association last year by Dr. F. R. Packard of Philadelphia, dealing with the fatal results of operations upon the nose and throat. Dr. Knight stated that all were quite ready to accept the conclusion in the paper referred to, that meningitis as a complication of intranasal operations should not be lightly regarded. In the case reported by the authors the precise source of infection was difficult to trace. The usual precautions as regards cleanliness and asepsis were observed. It did not seem that the patient suffered an excessive degree of surgical shock, and so far as could be discovered she was not subjected to any special exposure. It was suggested that certain pathogenic conditions of unusual virulence found their opportunity in an organism of low resisting power. The case was reported at length. An interesting point was that there were no chills, nausea, or vomiting throughout the entire course of the disease.

**Further Report on a Case of Lupus of the Pharynx and Nasopharynx.**—Dr. HERBERT S. BIRKETT of Montreal said that the first report of this case was made before the American Laryngological Association in 1904. The author saw this patient in May, 1904. At that time the lesions which had shown themselves in the nose, ear, and nasopharynx had entirely disappeared. In December of the same year the patient again presented himself at the Out-patient Department of the Royal Victoria Hospital. He came merely to report. Examination of the sites of the former lesions, viz., the ear and nasopharynx and the cartilaginous portion of the septum, showed the local conditions to have remained absolutely healed, and the only indications of their former presence were fine, linear cicatrices. Upon examination of the larynx the epiglottis was noticed to be swollen and infiltrated, and its surface studded with minute infiltrates, pinhead in size. At the extreme end of the epiglottis these infiltrations stood out clearly, but proceeded from this point to the body of the epiglottis after gradually becoming smaller, and merged into the smooth surface of the mucous membrane. The epiglottis was so swollen and enlarged that when lying in a quiescent state it came in contact with a point directly opposing the posterior wall of the pharynx. In this portion of the pharynx a small ulcer was noticed, in size about 7 mm. wide and 5 mm. broad, and in outline almost circular, the edges of which were infiltrated with small round nodular thickenings, corresponding closely in color with those on the edge of the epiglottis. The patient was entirely unaware of the newly existing conditions in the throat. There was no question from the appearance of the local trouble that the same pathological process which had existed in the upper portions of the respiratory tract were now making themselves known in another region. The application of the *x*-rays was at once begun. They were applied externally through the tissues of the neck corresponding to the parts infected within. The applications were made four times a week, their duration being increased from ten to twenty minutes. This treatment had resulted in cicatrizing all the right half of the epiglottis. This had persisted satisfactorily toward the remainder of the epiglottis, and the ulceration on the posterior wall of the pharynx had been so far diminished in size that it now measured 3 x 2 mm. In the previous report of this case a brief note was presented of a patient suffering from lupus of the nose which, before coming under observation, had destroyed the greater portion of the nose and had infected the epiglottis in a similar process. *X*-ray treatment was instituted in this case also. The patient had been seen quite recently, and there was a complete disappearance of the lesion with the result, however, that it had left the epiglottis destroyed to half of its extent. The author thought that with a fair amount of justice one might look upon the results obtained in these two cases as sufficient to warrant the trial of this treatment in place of so many other therapeutic measures, the results of which have been anything but satisfactory.

**The Treatment of Acute Inflammations of the Nasal Accessory Sinuses.**—This paper was presented by Dr. THOMAS HUBBARD of Toledo, who dealt with the subject in a most comprehensive manner. Attention was called to the fact that in individuals weak in resistance there might be a chronic purulent condition, and a virulent attack of purulent sinusitis in such cases might terminate in a catarrhal flux. Reference was made to the various conditions which might cause acute inflammation of the nasal accessory sinuses. With regard to the treatment of such inflammations, the author had found that bicarbonate of potassium in doses of 20 to 30 grains, administered in an ounce of camphor water in a half teacup of water every two hours was especially efficacious. In severe general sinusitis dry heat, even when applied continuously, gave but little relief, and moist heat should be advised according to the following manner: Cover the eyes with pads of dry cotton and then poultice the face thoroughly as hot as can be tolerated, making four changes an hour for about two hours. Then dry the surface and apply a mask of quilted cotton, holes having been cut for the eyes. This latter precaution is essential, whether dry or moist heat is used. The primary effect of this treatment might be to increase tension pains, but there was no doubt that it relieved venous and lymph stasis even in the deeper tissues, and soon there would follow evidences of resolution, and bone pains and neu-

ralgia were alleviated. This should be repeated with intervals of two or four hours' rest until general resolution had been established. It might even then be necessary to apply moist heat once daily for several days, since there was usually a period of daily tension pains due to filling of certain previously drained sinuses. In the interval between the hot applications it was advisable to apply a vasogen-camphor-chloroform preparation, rubbing this into the skin of the forehead and nose and superior maxillary region, the cotton mask being reapplied. The use of the nasopharyngeal douche was most strongly deprecated. The author also entered a protest against the indiscriminate use of chilling sprays, such as cold detergent solutions and methyl oil sprays, as the reaction was decided, and mucoperiosteal pain was increased following the shock of the cold blast. It was the author's opinion that all applications to the nares should be warm and applied without force. He described one method of using a douche which prevented the fluid from reaching the nasopharynx, and which in selected cases might be used satisfactorily in general sinusitis. The head should be held face downward so that the floor of the nares was vertical; the nostrils were immersed in a two-ounce glass full of carbolized, cocainized, tenth-normal saline solution of 105°, and then by closing one nostril with pressure on the ala and exerting gentle suction, a solid volume of the warm solution could be drawn up into the anterior third or half of the nasal chamber, and then allowed to flow back into the glass. Dr. Hubbard advised that since there seemed to be a decided tendency to recurrence of localized sinusitis with each attack of severe coryza, in the interval following the attack any obstruction to free drainage should be removed.

**An Intranasal Operation for Draining the Frontal Sinus.**—Dr. E. Fletcher Ingals of Chicago, called attention to a procedure which he believed of great value, presenting four cases illustrating its technique and showing its results. He did not offer this method as a certain cure for chronic suppurative sinusitis, but stated that it was safe, efficient, and caused no secretion. He recommended it in suitable cases after establishing free drainage, an essential factor in the curative treatment of every case. He had devised a special instrument, which he minutely described, detailing the operation step by step. With this instrument in the performance of this operation, he secured most gratifying results.

**A Case of Vaccination in the Nostril.**—Dr. Francis R. Packard of Philadelphia presented a picture illustrating this case. The patient had scratched the original vaccination point with the finger nails, and had then, before washing her hands, scratched or picked her nose, causing an accidental vaccination in the nostril.

**Symposium on Sinus Disease.**—In this the two following questions were considered: (*a*) What symptoms in diseases of the nasal sinuses demand radical surgical intervention? (*b*) What have been the comparative results of conservative and radical methods of treatment?

**The Maxillary Sinus.**—Dr. Robert C. Myles of New York gave it as his opinion that radical surgery should be employed in nearly all cases of exposed bone necrosis beneath the periosteum and at the roots of the teeth; in all cases of extensive polypoid changes in the mucosa; in all cases of osteomyelitis. Nearly all cases of neoplastic growths required extensive radical surgery. The earlier and more complete the surgical procedures, the more favorable the results would be. Dr. Myles said he had performed several hundred operations through the canine fossa and malar route, more or less thoroughly curetting the anterior cells, but had now practically abandoned this procedure. With regard to the comparative results of conservative and radical methods of treatment, radical treatment was supposed to remove the pathological condition as well as the cause, or root of the disease, and to leave no ground for a future disease condition. After experiments carried on for many years, it was found that the irrigation method through the normal opening produced a cure in a number of patients, but the treatment was too slow and uncertain to merit more than occasional favor. Such good results had been secured in this class of cases by a conservative operation that the writer in almost every instance used it as a curative procedure, or as a preliminary operation to the more extensive one. This conservative treatment consisted of an operation with curved chisels, which cut going in and coming out, the use of the rongeur forceps, with the occasional aid of the electric trephine. As much as possible of that part of the anterior nasal wall which was situated within the inferior meatus was removed, and in certain cases it was best to remove a part of the inferior turbinate. After irrigation, the cavity was thoroughly curetted and packed with iodoform gauze. The cavity was irrigated through this opening until the discharge practically ceased. The author stated that in a series of cases in which this procedure was followed better results were obtained than after the other methods.

**The Maxillary Sinus.**—Dr. George A. Leland of Boston reported a case of chronic empyema of the antrum of Highmore. The patient was a woman, thirty years of age, who had suffered for nine months previous to operation with pain, headache, vertigo, insomnia, foul discharge, etc. In this case the dentist had perforated the alveolar process above and anterior to the first molar, a perfectly sound tooth. This perforation gradually closed, so that the drainage tube could not be reinserted, and the dentist then passed in a roll of rubber dam. This was lost. After this, syringing was continued through the aperture until it became so narrow that it was impossible to introduce the probe-pointed syringe. The suffering at this time began to be more intense, but operation was delayed because of a soon-expected confinement. It was notable that transillumination showed this side as clear and bright as the other, evidencing that the antrum was full of polypi, the layers of pus being too thin, however, to cast a shadow. At the operation the canine fossa was entered, the anterior wall resected up to the infraorbital formation, and an enormous mass of polypi curetted out, together with the rubber dam. The anterior end of the lower turbinate was removed, and a large opening made into the nose. The cavity was packed with iodoform gauze, and the external wound sutured. Although the interior of the nose soon appeared in a satisfactory state, the vertigo continued, and the headache was very intense—in fact, so severe that the second turbinal had to be almost entirely removed because it pressed on the septum. The patient still suffered, and there was an annoying formation of crusts, which required constant care. There was no evidence of other sinus disease. A notable result of the operation was that the area of the cheek just external to the nose and the lip below it still was anesthetic. Another case was presented of far less severity, but in which radical treatment was called for. This patient was still annoyed by crust formation on the stumps of the turbinals, though the antrum was dry, and a probe introduced through this opening in the outer nasal wall showed it to be nearly filled with fibrous tissue covered by a mucous membrane, apparently healthy. Dr. Leland dealt comprehensively with the etiology and treatment of these affections, going into the subject quite exhaustively.

**The Frontal Sinus.**—Dr. Cornelius G. Coakley of New York mentioned the following symptoms in acute frontal sinusitis as demanding external opening of the sinus: (1) Edema and redness of the upper eyelid, accompanied by throbbing pain over the sinus with tendency to increase in severity after more than twenty-four hours from the resection of the anterior third of the middle turbinate, and the thorough contraction of the mucous membrane in the middle meatus by means of local applications of adrenalin and cocaine. (2) Marked prolapse of the orbital wall of the frontal sinus. (3) Displacement of the globe of the eye downward and outward, accompanied by diplopia. (4) The development of a fistula at the upper angle of the

orbit, as evidenced by redness, great swelling, and fluctuation in this region. (5) Intense supraorbital and frontal pain, which cannot be relieved by establishing drainage through the nasofrontal duct, with a tendency to an elevation in temperature, and symptoms of beginning inflammation. In answering the question regarding the comparative results of conservative and radical measures, Dr. Coakley stated that the above-enumerated symptoms were not very frequently encountered. In a series of fifty-eight cases of acute frontal sinusitis occurring in his private practice between January 1, 1903, and January 1, 1905, fifty-four made complete recoveries as a result of intranasal treatment, such as the excision by forceps and snare of as much of the middle turbinate as lay anterior to the opening of the nasofrontal duct in the middle meatus of the nose, in conjunction with the use of douches of hot normal solution, and the local contracting effects of adrenalin and cocaine applications. One fatal case was cited, which was seen forty hours after the onset of the attack. The patient died twenty-three hours later from an acute meningitis, with symptoms of great intracranial pressure. In this case the anterior third of the middle turbinate was excised, and, judging from the discharge, drainage was good. It was believed that the infection of the meninges occurred prior to the time when the patient came under observation. Another fatal case was also recorded, and two successful ones. In chronic frontal sinusitis the following symptoms were given by the author as demanding radical operation: (1) Chronic suppurative frontal sinusitis accompanied by a multiple polypi formation in the nose. In elderly people, or those with marked organic lesions of the heart, lungs, or kidneys, a radical operation might be inadvisable. (2) In severe acute exacerbations of the chronic condition whenever any of the symptoms enumerated under acute frontal sinusitis develop. (3) If intranasal treatment of a frontal sinus does not suffice to prevent the discharge from passing into the antrum, and the odor and taste of the fetid discharge from the latter annoy the patient, then, in order to cure the antrum, the frontal sinus must be operated upon radically. (4) Very large frontal sinuses with multiple septa, and particularly those with recesses extending backward over the roof of the orbit, can be but imperfectly irrigated. Skiagraphy will give the exact height and breadth of the frontal sinus, indicate the number and position of the septa, and, in many cases, give evidence of an orbital recess. The radical operations should be advised for such patients. (5) Patients with narrow nasal cavities offer greater difficulty in carrying out intranasal treatment than those with more patent nares. (6) In certain cases where the patients desire to be cured as quickly as possible a radical operation is advised, for, although it may take as long to effect a cure, when the cure is once obtained it is permanent. (7) The neurasthenic patient who is prostrated each time intranasal treatment is attempted and rarely submits to enough being done at any one time to make much progress, is more satisfactorily treated by the radical method. There is seldom any pain after the second dressing by the latter method. (8) If a fistula has formed leading into a frontal sinus, a radical operation is the only treatment likely to effect a cure. Dr. Coakley briefly mentioned the conservative treatment, the radical treatment, the Kuhnt, the open, and the Kilian operation.

**The Frontal Sinus.**—Dr. William E. Casselberry of Chicago, in dealing with this subject, spoke of the radical and conservative methods, mentioning the statistics collected from the literature on the question of brain complications from frontal sinusitis. The demand for radical surgical interference was imperative, the author believed, if there were actually present symptoms of commencing intracranial infection, such as severe, persistent headache, chills, fever, centric paralysis, etc., but the mere indefinite chance complications of this kind did not necessitate an external operation without additional valid reasons, in so much as one risk might be said to balance the other. Hence, it was stated that the intranasal or conservative methods were especially suitable for latent and mild chronic uncomplicated single sinus suppurations. The question of sinus suppuration being contagious was alluded to. It was the writer's belief that certainly the recurring attacks of tonsillitis and erysipelas, to which sinus patients were prone, were communicable to others. Other reasons mentioned for the external operation were persistent failure of the general health or impaired vitality from septic absorption, serious mental depression, destruction of the sinus, abscess of, or encroachment upon, the orbit, external fistula, impermeability of the nasofrontal duct, syphilitic necrosis, inveterate multiple sinusitis, and economic conditions or occupations which precluded the more tedious methods. Dr. Casselberry advised, however, that the conservative methods should be tried even in such instances. To illustrate these questions, he very briefly reported sixteen cases. Summarizing the results of the conservative treatment in these cases, he said that six were of mild type, and these were now well; of the remaining ten typical severe cases, only one could be called cured; two were much improved, suffering but little inconvenience; three more were somewhat improved, but were still dissatisfied, and the remaining four were unbenefited.

**The Ethmoidal Sinus.**—Dr. John O. Roe of Rochester, N. Y., after discussing the various sinuses, their construction and diseases, mentioned the presence of pus or pain as indicating the necessity for radical surgical interference. He said that acute inflammatory conditions rarely demanded surgical intervention, except where they were engrafted upon chronic condition, as in the case of a fresh infection superimposed on a chronic catarrhal process or a chronic empyema. In other cases where an acute condition became chronic and purulent, resisting all local treatment of a detergent or antiseptic nature, radical measures were demanded. Dr. Roe reported a case in which there was found a condition of chronic inflammation and infiltration in the posterior ethmoid region, which could only be approached in the most cautious manner, but in which finally the infiltrated structures were safely removed. He laid great stress upon a frequent source of infection of cells in sinus disease, viz., the forceful blowing of the nose during a coryza, or while infected with an influenza. He considered the use of the sharp curette dangerous, except in cases of polypoid growths within the cells. He stated that in all ordinary cases of ethmoid disease the cells could be freely and safely opened by means of Grünwald's punch forceps, with the assistance of the probe, to determine the parts requiring removal, and that it was in those cases only which are complicated by disease of the frontal sinus that the external operation was required. Dr. Roe advocated radical measures in the treatment of diseases of the ethmoid cells attended by the symptoms of pus or pain, as in such operations the abscess cavity was properly opened, thoroughly drained and medicated, the danger of infecting other sinuses or parts was avoided, and recovery was comparatively certain, speedy and permanent.

**The Ethmoidal Sinus.**—Dr. John W. Farlow of Boston summarized the symptoms calling for surgical intervention as follows: Severe or long-continued headache, disturbances of vision, displacement of the eye, orbital abscess, inflammation of the meninges, syphilis and forms of necrosis, obstinate polypi, especially when combined with polypoid degeneration of the middle turbinal, frontal disease caused by ethmoidal obstruction, pus in the antrum of ethmoidal origin, severe or obstinate forms of ethmoidal suppuration with pus flowing into the postnasal space causing laryngitis, bronchitis, asthma, or other disease of the upper air passages. He believed that the removal of a considerable portion of the middle turbinate followed by opening and curetting of the cells was very satisfactory in nearly all ethmoidal affections, even the severe forms, although a certain amount of discharge might persist after the active symptoms have been relieved. He was not in

favor of too vigorous treatment, especially in the region of the orbit or the cribriform plate, as an element of danger was unnecessarily added to the symptoms of the patient. In Dr. Farlow's experience, it had not been necessary or advisable to operate externally except where there was an orbital abscess, or where the pus had already formed or was on the point of forming an external opening, say, at the root of the nose. He had seen cases of syphilis and necrosis where an external opening was necessary in order to remove the diseased bone.

**The Sphenoidal Sinus.**—Dr. J. W. Gleitsmann of New York detailed the symptoms of acute and chronic affections of this sinus. He mentioned several reports of cases of secondary hemorrhage. It was stated that although secondary hemorrhages due to extravasation from other localities were not so infrequent, primary hemorrhages were, according to Citelli, very rare, there only being six cases on record. Dr. Gleitsmann upheld the theory of radical measures in vital affections of the sphenoidal sinus.

**The Sphenoidal Sinus.**—Dr. T. Passmore Berens of New York presented a paper on the comparative results of conservative and radical methods of treatment of diseases of the sphenoidal sinus, and reached the following conclusions: (1) Acute uncomplicated empyema of the sphenoid sinus is amenable to conservative treatment provided that the ostium is accessible through the nose. (2) Acute multiple sinusitis involving the sphenoid is amenable to conservative treatment provided drainage is not blocked by anatomical deformities or diseased conditions. Anatomical deformities may render surgical procedures necessary to gain access to the ostium. (3) Acute or chronic pyosinus of the sphenoid can be cured only by the removal of its cause, and that is by treatment of the disease of the ethmoids. (4) Simple chronic empyema of the sphenoid sinus alone, when unaccompanied by serous tissue, changes in the interior of the sinus, is amenable to conservative treatment. (5) Chronic empyema of the sphenoid sinus when it occurs as a complication of diseases of other sinuses, as it frequently does, or when accompanied by tissue changes in its interior, can be cured only by radical procedures involving not only the destruction and removal of all the tissues diseased, but also the removal of all other tissue that may be a hindrance to drainage and to after treatment. (6) The tendency of the anterior wall of the sphenoid sinus to reform is a sufficient warrant for as complete a removal of it as possible. (6) The location of important vessels in the region of the sphenoid is a strong argument in favor of the maxillary route when the antrum is involved, for this route gives double access to the sphenoid sinus, and thus the more readily permits of proper instrumentation.

**The Deflection of the Nasal Septum in Children.**—Dr. Arthur Ames Bliss of Philadelphia read a paper with this title. He discussed the subject most thoroughly, its causes, results, and the conservative and radical measures to be employed in such cases. This paper brought out a great deal of most interesting discussion in which were reported several cases by the various members of the association. Dr. Bliss also presented a photograph, showing three pieces of rubber tubing used as supports for the septum after resection operations.

**A Second Note on a Case of Sarcoma of the Nose.**—Dr. J. Price-Brown of Toronto presented this case, and also reported two others. The first case was operated upon for this condition ten and one-half years ago, and except that the right nasal passage, from which the growth was removed, was always so open that it sometimes became dry, and that the slightest cold blocked up the left passage so effectively that the patient could not breathe through it at all, he was absolutely well. The second case was that of a man fifty years of age, in whom the growth was situated on the left side of the perpendicular plate of the ethmoid. This was removed, as in the first case, by the electrocautery. It had now been two years and nine months since the operation, and there was no return of the growth. The third patient was one on whom a note was made before this association two years ago. The patient had been under observation for several years, and the growth had returned from time to time, although it each time had been relieved for several months. After the first operation there was an interval of four months of good health; after the second operation an interval of six months, and after the third operation there had so far been a period of nine months. The patient at present was in good health, with no evidence of recurrence. Each removal of the growth in this case was done by the electrocautery.

**A Further Study of Hay Fever Clinically, with the Employment of Pollantin.**—Dr. Alexander W. MacCoy of Philadelphia read a paper with this title, giving his experience with Dunbar's antitoxin serum.

**Tonsillotomy, the Basis for the Treatment of Tonsillar Affections.**—Dr. George B. Hope of New York recommended the early removal of the tonsils. It was stated that there is still great uncertainty as to the physiology of this organ, and that some investigators took the radical view that there were no tonsils in the healthy throat. The author believed their removal as a prophylactic measure was warrantable, since when left until a time of necessity their removal was much more difficult. He further showed that the operation of tonsillotomy was practically without danger, there being but four fatal cases on record. In a study of the statistics of the Metropolitan Throat Hospital, Dr. Hope found that in a series of 2,000 cases, in but two was there free hemorrhage so marked as to be placed on record. Dr. Hope's chief point was that in his opinion it was wise to remove the tonsils, as they had no known work to perform, and were a source of easy infection.

**Two Cases of Gangrene of the Tonsil.**—Dr. Charles W. Richardson of Washington, D. C., said that one of these cases had been previously reported in a paper read by title before this association two years ago. He also presented abstracts of the only three other cases found on record under the head of "gangrene" of the tonsil. He considered himself rather fortunate, this being apparently so rare a condition, in having seen two such cases within fourteen months. He stated that the diagnosis was easy, the characteristic odor, once recognized, was never forgotten, and the physical signs and constitutional manifestations were very positive.

**Sequel to a Case of Epithelioma of the Larynx, Shown to the Association Two Years Ago.**—Dr. Walter F. Chappell of New York stated that the first report was of a thyrotomy for malignant disease, after which the patient recovered good health. Since this report was made he had undergone tracheotomy and laryngectomy for malignant growth in the larynx, but was now in excellent condition, and could carry on a conversation at a distance of six feet. He still wore a tube, however. The author presented a detailed account of the growth removed at the primary operation.

**Foreign Body (Impacted) in the Esophagus.**—Dr. Gordon King of New Orleans reported these two very interesting cases. In the first one, a child of two years, the foreign body was a patent, brass bachelor's button, and was removed by the use of forceps, although the mouth of the esophagus and posterior surface of the larynx were somewhat lacerated. The child recovered. The second case was that of a sailor, thirty-four years of age. In this instance esophagotomy was done, and a large, jagged piece of bone, which was the foreign body, was removed with forceps. The after-course of this case was unfortunate, the patient developing an empyema of the thorax. He was still under treatment for the latter condition. Dr. King protested against the indiscriminate use of the Graefe coin-catcher except in skilled hands and in selected cases. He believed its use should be limited to cases of foreign bodies of the flat, circular variety, such as coins and buttons, and if the exact nature of the foreign body was not known it should be determined by means of the *x*-ray or the eso-

phagoscope. The author was a strong advocate of the latter instrument.

**Papilloma of the Larynx in Children.**—Dr. J. Payson Clark of Boston reported fourteen interesting cases of this condition. He summarized his views by saying that papilloma of the larynx in children was a very serious condition, the cause of which was unknown. The best method of treatment in all cases was tracheotomy and non-interference with the growth. If after this treatment it still persisted after an age when the child would be treated as an adult, it had probably lost its activity of reproduction, and attempts at removal might be made.

**Rest in the Treatment of Laryngeal and Pulmonary Tuberculosis.**—Dr. W. Peyre Porcher of Charleston, S. C., urged complete rest in all cases of laryngeal tuberculosis or any severe affections of the larynx. He reported a case in which he tried this method of complete rest, with suitable medication, and in which the outcome was most successful. This result was obtained without special reference to climate.

**The Relation Between Laryngeal and Pulmonary Tuberculosis.**—Dr. Walter F. Chappell of New York in a second paper presented a lengthy but comprehensive article on this subject, dealing with the various methods of infection in which both organs might either be infected from a common source, or in which one organ might infect the other. He presented the following factors which made possible a tuberculosis of the larynx of independent origin: (1) Direct, prolonged exposure of the larynx to infected dust. (2) Penetration of tubercle bacilli beneath the superficial tissues whether by natural or artificial openings, or through the intact epithelial covering. (3) A lax, permeable state of the tissues in special cases, which permits tubercle bacilli to enter in large quantities and reach the submucous lymphoid tissue. (4) Ability of the tubercle bacilli to survive for a long period in these tissues without causing active changes. (5) Rousing of bacilli to virulence by a lowering of vitality incident to anemic or cachetic states, etc. (6) Coincidence of mixed infection, which not only promotes the virulence of tubercular bacilli, but determines many of the clinical forms of the local disease.

**A Case of Complete Adhesion of the Vocal Bands with Laryngeal Stenosis Following Diphtheria.**—Dr. D. Braden Kyle of Philadelphia reported this case. The patient, a child, aged six years, had worn a tracheotomy tube for nine months. Laryngeal examination showed a fairly free movement of the epiglottis, but the lumen of the larynx was entirely occluded. There was complete absence of phonation. A fenestrated tracheotomy tube was first introduced to determine whether any air passed through the larynx, and it was found that the child could not get the slightest amount of air by this route. The patient was then anesthetized, the tracheotomy wound enlarged, and a pair of small, slightly curved hemostatic forceps gradually worked up through the structures until the end of the instrument could be felt distinctly by the finger beneath what should have been the vocal bands. This structure was then separated by means of a short curved bistoury and the laryngeal dilator introduced. An extra long intubation tube was then inserted into the larynx and extended below the tracheotomy wound. The tracheotomy wound was temporarily closed by adhesive strips, and the child breathed perfectly through the intubation tube. After three or four minutes the respirations began to diminish, and grew more shallow and less frequent until its condition became alarming. The temporary dressing was removed and the intubation tube withdrawn. Under artificial respiration the child quickly recovered. The intubation tube was introduced a second time with the same results. Dr. Kyle concluded that this inhibitory action of the respiration was due to pressure of the intubation tube on either the recurrent laryngeal, or else on the internal branch of the superior laryngeal nerve, and decided to abandon the attempt to establish laryngeal breathing by the above method, and at a later date split the larynx and dissect out the obstructing tissue. The child rapidly recovered from this operation, and was able to quite distinctly pronounce several words, but the speech was largely limited to lip enunciation. The child was allowed to leave the hospital, arrangements being made for its return in a week for the second operation, but, unfortunately, it contracted a severe cold, and developed pleuropneumonia and died in twenty-four hours. The two points of interest in this case were (1) the inhibition to respiration caused by the pressure of the intubation tube, and (2) the interesting histopathologic condition of cartilaginous cell formation within the inflammatory structure.

**Rogers' Modification of the O'Dwyer Treatment of Chronic Stenosis of the Larynx.**—Dr. D. Bryson Delavan of New York stated that he believed that in this modification Dr. Rogers had opened a new era in the history of chronic laryngeal stenosis, and had illumined every department of the subject. He had made valuable additions to the O'Dwyer tube itself, having devised an attachment to it which rendered its use possible in cases where the ordinary O'Dwyer tube could not be retained. The author reported twenty-two cases which emphatically established the success of this modified method.

**Papilloma of the Nasopharynx Simulating Epithelioma.**—Dr. Thomas J. Harris of New York reported a case which was of interest, particularly on account of the rarity of this condition, and he briefly mentioned three other cases collected from the literature.

**Fibroma of the Larynx in a Child of Three Years, Necessitating Tracheotomy; Subsequent Laryngo-Fissure for Removal Followed by Prolonged Intubation.**—In a second paper by the same author the following conclusions were reached: Fibroma of the larynx is not a particularly rare form of tumor, occurring only second in frequency to papilloma, according to Sir Felix Semon. Cases of fibroma in children are, however, rare, and we have failed to discover a similar case where tracheotomy was called for on account of the degree of dyspnea. Again, while laryngofissure is regarded as one of the forms of procedure in exceptional cases of multiple papillomata, we do not recall a case where it has been practised in an infant for fibroma. Since operating upon this child, the author had come to the conclusion that it might have been wise to have removed the tumor intralaryngeally by means of the Dundas-Grant safety forceps, either under cocaine or under ether, although the possibility of wounding the vocal cords was, of course, to be considered. The child now seemed to be entirely well, although a year must elapse before a relapse could be excluded.

**Laryngeal Diphtheria in an Adult (Necessitating Intubation) Complicating Cerebrospinal Meningitis.**—Dr. W. K. Simpson of New York reported a most interesting case, through which he wished to demonstrate that cerebrospinal meningitis and true diphtheria might coexist in the same patient, and that the respective bacilli were not necessarily antagonistic one to the other. The importance of recognizing this fact was very timely, owing to the existing belief that it was impossible.

**An Unusual Case of Edema of the Glottis.**—Dr. Emil Mayer of New York reported this case. The patient was a man aged 51, admitted to the hospital with a diagnosis of dyspnea. He had had a chronic cough, with mucopurulent expectoration, never bloody; no night sweats or dyspnea; no swelling of the feet. Had never had syphilis or gonorrhea. The voice had always been clear. He had never had an attack like the present one, but had waked at night with a sensation of choking, which he attributed to cough. The present attack of dyspnea came on suddenly; in spite of leeches to his neck and cups to his chest, he rapidly became worse. His voice was that of a whisper. He was removed to the hospital on the day following; on admission he had severe inspiratory dyspnea, and could not lie down. Lips and fingertips were cyanosed. There was a profuse mucous discharge from mouth and throat; the breath was fetid, and

the epiglottis could be felt as a thick, hard ridge. When Dr. Mayer saw him, two hours later, the patient's expression was anxious, he was cyanotic, his breathing was very labored, with notable inspiratory difficulty. There was a gurgling sound to each inspiratory effort, and quantities of mucus were expelled. Laryngoscopic examination showed a large, glistening mass at the base of the tongue at the right side, filling the entire pyriform sinus on that side, extending over the epiglottis to such an extent as to leave but a narrow opening on the left side for breathing. An intralaryngeal examination was impossible. Diagnosis of an acute septic inflammation was made, the parts were partially cocainized, and a deep incision was made with the Hartman laryngeal knife. A quantity of thick, bloody, and ill-smelling fluid exuded, and the patient was returned to the ward. A spray of adrenalin, 1-5,000, was frequently applied, alternating with steam inhalations. The distress was relieved, breathing becoming quieter hour by hour, and all inspiratory difficulty ceased on the second day. At this time a laryngoscopic examination showed a large white slough where the edematous mass had been. A portion of this was removed, and examination showed the presence of staphylococcus albus and streptococcus. The dysphagia also became less and less, and there was now a solid mass of new growth of firm consistency lying in the pyriform sinus, covering three-quarters of the epiglottis, but not adherent thereto, and which did not interfere with deglutition or respiration. The glands of the neck were not enlarged. The patient's recovery was rapid, and he was discharged two weeks after admission, although he subsequently came to the Out-Patient Department of the hospital for treatment. The pathological report of two specimens of the growth was that there was no evidence of anything other than connective tissue in either specimen. An examination of the patient six weeks later showed a most unusual state of affairs. More than half of the epiglottis on the right side had sloughed away, and a band of adhesion had formed, running across the lateral pharyngo-laryngeal space on that side. The remaining portion of the epiglottis on the left side stood erect like an index finger, and here two bands of adhesion existed from the epiglottis to the lateral pharyngeal wall. Both of these bands were about half an inch in length. The patient, however, appeared to be perfectly well. An interesting point in this case was the fact that there was an edema of the glottis engrafted upon a hereditary syphilis of the epiglottis, the latter never producing any notable symptoms relative to the throat, except perhaps a constant cough of twenty-eight years' duration. The patient stated that fluids often came through his nose of late years. The presence of so large a mass of inflammatory tissue beneath an edematous process is remarkable. The case illustrated the advantage of performing free and deep incisions into the edematous tissue, thus avoiding the greater operation of tracheotomy, and emphasized the value of adrenalin in the subsequent treatment of these conditions.

**Recommendations for Fellowship.**—The Council recommended the following candidates for election to active fellowship in the American Laryngological Association: Dr. Lewis A. Coffin of New York City. Thesis, "The Choice of Operation for the Relief of Chronic Empyemata of the Frontal Sinus and the Anterior Ethmoidal Cells." Dr. Otto T. Freer of Chicago, Ill. Thesis, "Deflections of the Nasal Septum; A Critical Review of the Methods of Their Correction by the Window Resection, with a Report of 101 Operations." Dr. Charles P. Grayson of Philadelphia, Pa. Thesis, "Some Follies of Vocalists." Dr. Thomas H. Halsted of Syracuse, N. Y. Thesis, "Angioneurotic Edema of the Upper Respiratory Tract." Dr. George L. Richards of Fall River, Mass. Thesis, "My Personal Experience with Empyemata of the Frontal Sinus, with Deductions Therefrom." Dr. George B. Wood of Philadelphia, Pa. Thesis, "The Lymphatic Drainage of the Tonsils."

The date and place of the next meeting were left to the action of the Council.

**Officers Elected.**—*President,* Dr. J. W. Gleitsmann of New York City; *First Vice-President,* Dr. J. L. Goodale of Boston, Mass.; *Second Vice-President,* Dr. Charles W. Richardson of Washington, D. C.; *Secretary and Treasurer,* Dr. James E. Newcomb, of New York City; *Librarian,* Dr. Joseph H. Bryan of Washington, D. C.; *Council,* Dr. Clarence C. Rice of New York City.

## BRITISH MEDICAL ASSOCIATION.

*Seventy-third Annual Meeting, Held at Leicester, July 25, 26, 27, and 28, 1905.*

(Special Report to the MEDICAL RECORD.)

*(Continued from page 361.)*

### SECTION OF TROPICAL DISEASES.

*First Day—Wednesday, July 26.*

**Guinea-worm and Its Hosts.**—Dr. W. H. GRAHAM presented a communication on this subject. He said that in 1904, while studing the incidence of the disease at Gambaga in the hinterland of the Gold Coast Colony, he was struck by the preponderating importance of guinea worm as a cause of disease. A tabulation of the statistics of guinea worm for 1904 and three preceding years showed that the month of June was the month of greatest incidence and that from this month backwards and forwards the incidence of the disease declined to zero. Now, as the Guinea-worm requires for its propagation the alternate services of two hosts, man and cyclops, the induction appeared legitimate, that the month of maximum manifestation in man should be the month of maximum infection of cyclops. Fedschenko had shown that in Turkestan the Guinea-worm embryos required five weeks for complete development in cyclops. Embryos therefore beginning this development in June would become capable of infecting man in July or August of the same year. Further as the parasite acquired by man in July or August would become manifest by discharging embryos in the following May or June, it would appear a legitimate inference that ten months represent roughly the period required by the Guinea-worm for its complete development in man. If then the infection of the cyclops with Guinea-worm occurs during the months of May and June, it becomes worth while to inquire whether during this period any natural facilities are afforded to the process of infection which are subsequently withdrawn? To answer this question an intimate acquaintance with the habits of cyclops and a minute knowledge of the locality is necessary. At Gambaga almost all of the water used by the natives was drawn from three wells situated about half a mile from the town. These wells contained subsoil water only and were very greatly influenced by drought and rainfall. They were connected by streams that flowed during the greater part of the year. During the last few months of the dry season these streams dried up and then the communication between the wells ceased, in some cases altogether and in others during the daytime only. Dr. Graham noticed that cyclops inhabited the streams and wells alternately and that it bred in the wells. He believed that the young of the cyclops whilst moulting during development afford greater facilities for penetration by the Guinea worm embryo and thus explained the limitation of the infection for cyclops to a few months of the year. August and September were the months of greatest rainfall at Gambaga. At the end of September, or earlier, according to the rainfall, the wells become full and the increased current swept the cyclops of the wells into the streams. In a pool of clear water the cyclops kept mostly close to the bottom. When the level of the water in the well was low, the calabash used for drawing the water was swept near to or against the bottom, and this facilitated the taking of cyclops; but at the end of September the volume of water in the well was large, and the water being therefore drawn from the top, the cyclops in the well were less easily caught by the calabash. Speaking of prophylactic methods, Dr. Graham stated that to prevent the infection of man drinking water should

be filtered, and to prevent the infection of cyclops it would be necessary to make structural alterations converting the existing wells into concreted troughs.

Dr. W. M. Carnegie Brown said that in the Straits Settlements a unique opportunity for studying some points in the life history of the Guinea-worm was presented by the circumstance that in the Malay Peninsula there was no endemic infection of Guinea-worm. No one, so far as he knew, had ever acquired Guinea-worm in the Malay Peninsula. But many cases were to be seen there. Immigrants, natives of the Coromandel Coast, where the disease was endemic were frequent sufferers. Some idea of the length of time that it took for a female worm to mature, or more correctly to arrive at a stage of discharging her ova and thereby setting up suppuration, was to be had from observation of the length of time after the immigrants' arrival before the assistance of the surgeon had to be sought to evacuate a worm abscess. He had seen a case so late as eighteen months after arrival, and he had observed no periodicity, no greater seasonal frequency; the Guinea-worm turned up all the year round with fair regularity. In all such cases it was certain that infection took place in India before the patient left for the Malay Peninsula. Another point was the peculiarity of the fact that though *Cyclops quadricornis* was found in the meres and canals of the Malay Peninsula in considerable numbers, and though undoubtedly embryo Guinea-worms were discharged into these waters from infected persons, the cyclops seemed unable to develop the embryo or at least to render it hurtful to man. It did not act there as a host. The fact was peculiar and worth further study. Dr. Graham was apparently of opinion that a certain method of preservation was in seeing that drinking water was pure. That excluded the popular and he might also say the scientific belief that entry was gained by the skin. From analogy with other worms, this method was at least possible and the prevalent idea was that it explained the circumstance of nine-tenths of all the cases of Guinea-worm finding their favorite site in the legs, because infection took place while the patient was standing in water, which, needless to say, was an ordinary method of bathing. The question was not to be resolved by trying if Guinea-worm embryos could pass through the skin—they could not—but it was possible that after a specialization of function in the cyclops they might be able to do so.

Dr. Claus Schilling of Berlin said that one of his friends, a district commissioner and colleague, had many cases of Guinea-worm amongst his native soldiers in Togoland. After opening good wells and prohibiting the natives to take the drinking water from the places in which they used to bathe, the cases of Guinea-worm ceased almost entirely. This observation was in support of the opinion that the infecting germ entered the body by the alimentary canal.

Dr. F. M. Sandwith of London corroborated Dr. Graham's remarks with regard to the periodicity of the disease in man. Observers in the Egyptian Sudan had noticed that there are two or three months when human beings suffered from *Filaria medinensis*, while during the rest of the year the worm was not met with. He believed the embryo of this parasite could enter the human skin, and he urged those who dwell in Guinea-worm countries to try and prove the point as to whether the embryo could or could not gain direct entrance into man's body without passing through any species of cyclops.

Dr. A. J. Chalmers of Ceylon said he had noticed years ago the periodicity of the Guinea-worm infection in Accra, and had looked for infected cyclops without finding them. He had noticed one case of what he considered to be infection by the skin. He thought that the authorities of the tropical schools were not sufficiently alive to the importance of this disease.

Dr. J. T. Clarke of Perak said that in the Malay Peninsula the Tamils bathed in and drank everywhere the dirtiest of water and yet did not acquire the disease, although cyclops, according to Dr. Brown, were present.

Dr. C. Prout of Sierra Leone said he wished to emphasize what had been said as to the necessity of a more particular study of the mode of entrance of this parasite, as on the Gold Coast there was an enormous amount of inefficiency due to this cause, more especially among the Hausas. He had had experience of both the Gold Coast and Sierra Leone, and he had been struck by the fact that while Guinea worm was very common on the Gold Coast, it was very rare at Freetown. It was not a disease of Sierra Leone. Now there was one condition in which the Gold Coast differed from Freetown, and that was that in the latter there was a very pure and good water supply derived from the hills behind, whereas on the Gold Coast the water was mainly derived from surface water collected in pools and shallow wells. This would appear rather to support the theory as to the entrance into the body by means of drinking water.

Dr. L. W. Sambon of London said that the greater incidence of Guinea-worm manifestation had long been known to take place in connection with the rainy season. This was the case not only in West Africa, but in other parts of Africa, in Arabia, in Persia, in Turkestan and in India. The larvæ were eliminated at the beginning of the rainy season because water was necessary for their further development just as it was necessary to the cercariæ of the liver fluke (*Fasciola hepatica*) which left the host of their parent under the very same circumstances. This connection between water and the liberating of the young larvæ was emphasized by the fact that *Filaria medinensis* did not only perforate the skin of its host at the most favorable season, and in that part of the body which came most frequently in contact with water, but waited for the actual contact with water before extruding its young. This fact was well known to the natives of highly infected regions and had been acted upon from time immemorial for the extraction of the worm. In the case of *Fasciola hepatica* it was interesting to note that in very dry seasons the rediæ harbored in the liver of *Limnea truncatula* did not give birth to free-living cercariæ, but to a second generation of rediæ which continued to live in the host of this parent awaiting a more favorable season to venture into the outer world. The theory that the larvæ of *Filaria medinensis* penetrate the body of man through the skin was a very old theory, and certainly had much in its favor, notwithstanding that it was derived from an erroneous conception as to the reason of the peculiar location of the parasite in man. It was also supported by analogy since it had been amply proved by Looss, Smith, and others that *Uncinaria duodenalis* entered through the skin. Other parasites, such as *Strongyloides intestinalis* and certain Trematodes, may likewise enter the body of their host through the hair follicles of the skin. As Dr. Sandwith had remarked, the point should be settled by actual experiment. However, we should not forget that in the case of uncinariosis infection may also be acquired by way of the alimentary canal, as numerous experiments had proved. Not long ago it was firmly believed that the young larvæ of the warble-flies (*Hypoderma*) penetrated through the skin of cattle. Recently, however, Curtice had shown that they were licked by the cattle and that they penetrated the walls of the esophagus, and from thence moving slowly through the tissues of the host they reached the skin in the region of the back. In the case of *Filaria medinensis* Dr. Sambon doubted very much that the infection of man could take place by the immediate entrance of the young larvæ either through the skin or the alimentary canal. Professor Leuckart, from analogy with the life history of a similar parasite, the *Cucullanus elegans* of the perch, had suggested the necessity of an intermediary host, and had incriminated cyclops as the probable alternative host. Fedschenko, in Turkestan, had actually proved the truth of Leuckart's wise suggestion, and Sir Patrick Manson had confirmed it. The larvæ of *Filaria medinensis* having reached some pool or well, attacked the young cyclops, penetrated their bodies and underwent a certain amount of growth and development. This discovery was a decided step in our knowledge of the life history of *Filaria medinensis*, but it was only a step. So far the experiments

made by Fedschenko and others to bring about infection through the ingestion of infected cyclops had proved negative. Possibly cyclops was not the real intermediary host of *Filaria medinensis*, notwithstanding that the nematode might attain a certain amount of development in its body, or perhaps only certain species of cyclops could bring about its complete development; or, again, a second intermediary host might be necessary, or there might be another free-living stage and subsequent encystment, as in *Fasciala hepatica*. That ar intermediary host was necessary was shown by the peculiar limitations observed in the geographical distribution of *Filaria medinensis*, and by the fact that the parasite had not become established in many places which seemed to offer the most favorable surrounding conditions and in which it had been repeatedly and plentifully introduced during a long number of years, as, for example, in the Malay Peninsula, already mentioned by Dr. Brown.

*Second Day—Thursday, July 27.*

**Tropical Diseases of the Skin.**—Dr. J. M. H. Macleod of London opened a discussion on this subject. He went rapidly through the wide field of tropical dermatology, stating the theories held at the present time on the etiology of the various diseases, which he classed into four groups, according that (1) they were due to some known parasite, (2) were obviously parasitic, but the parasite had not been established, (3) were possibly parasitic, and (4) had a non-parasitic causation.

In speaking of frambœsia or yaws, a subject on which important information was elicited during the meeting, he stated that its virus was unknown, but that the clinical features and course of the disease all pointed to a parasitic origin. Various microorganisms had been found in the lesions, such as bacilli by Breda, micrococci by Pierez, Nicholas, Hirsch, and others, and a yeast by Powell. There was still some variance of opinion with regard to the occurrence of a primary lesion corresponding to the syphilitic chancre. Charlonis maintained that it existed, but this had been doubted. Nama Rat had described also certain symptoms of the type of the tertiary lesions of syphilis, consisting of subcutaneous nodules, ulcerations of palate and fauces, and bone diseases, but these were uncommon, and several observers denied their existence altogether, and maintained that such resulted from the concomitant infection of yaws and tuberculosis or syphilis. It was also at present under consideration whether yaws was a local disease or a constitutional affection, with skin lesions. The latter view seemed to be the one most generally accepted since Charlonis had shown that twenty-eight out of thirty-two persons inoculated with the disease suffered from "initial phenomena." including pains in the limbs, evening pyrexia, and other symptoms of general disturbance. Its relation to syphilis was still under discussion, since it had been maintained by several observers that the two diseases were identical, or that syphilis was yaws modified by life in a temperate climate, or, *vice versa*, that yaws was syphilis of the tropics. Till the microorganisms of yaws and syphilis were discovered, it was improbable that the last word in this controversy would have been said. Clinically and microscopically, the two diseases presented many points of similarity, but, after all, so did syphilis and tuberculosis. The facts that in certain countries, such as Fiji, loko or yaws occurred, while syphilis was unknown, that it was never a congenital affection, that although the skin lesions of yaws presented various stages in their evolution, but were not polymorphous as were those of syphilis, and, lastly, that the histopathology of the disease in a well-marked case was distinguishable from that of syphilis, all went to prove that we had to deal with two separate diseases.

**Yaws in Indo-China.**—Prof. M. E. Jeanselme of Paris contributed some "Notes on Pian (Yaws) in French Indo-China." The author saw the first cases of this disease in 1899 in Cambodia, where it is very widespread. Of all diseases syphilis most resembles yaws, so that Hutchinson and others had suggested that yaws was perhaps only a form of syphilis modified by race and climate. This opinion could not be accepted, partly because in the same part of the world and among natives of the same race the two toxins were found simultaneously, each preserving its distinct characteristics, and partly because Charlonis had furnished us with the undeniable proof of the duality of the two diseases by inoculating with syphilis an individual who was already suffering from yaws. However, it was quite true that the differential diagnosis was sometimes impossible. Among the signs which were common to both diseases were the pains in the bones and joints, which became worse at night, the tendency of the eruption to take a circular form, the preference for the neighborhood of the orifices of the body, and the curative power of iodide of potassium and mercury. The chief differences of the two diseases were shown in the following table:

| SYPHILIS. | YAWS. |
|---|---|
| Pandemic, and acquired by heredity and contagion. | —Tropical, and acquired only by contagion. |
| Begins by a primary pathognomonic lesion at the point of inoculation. | —The initial lesion is not constant, and is not different to later appearances. |
| The immunity conferred by syphilis is almost certain. | —Reinfection of yaws is possible. |
| Autoinoculation is impossible. | —Autoinoculation is possible during a long and unknown space of time. |
| A hard chancre and other syphilitic signs can be found on an individual who has suffered from yaws. | —A syphilitic person can become affected with yaws. |
| A great variety of eruptions. | —There is only one eruption, the papilloma. |
| The eruption, especially the tertiary form, damages the skin and leaves indelible scars after cure. | —The eruption leaves no scar behind it, unless it has been unduly irritated. |
| The three definite stages, with primary, secondary, and tertiary symptoms. | —All the appearances of yaws are identical, whatever their date. |
| The mucous membranes are involved. | —The mucous membranes escape. |
| The internal organs are affected. | —No affection in the internal organs. |
| There is no itching. | —There is much itching. |
| Hair falls out in the secondary stage. | —Hair never falls out. |

With regard to the curability of the two diseases by the same drugs, it must be remembered that actinomycosis, which, of course, has nothing to do with syphilis, is also cured by iodide of potassium. Unless some rare complications were present, yaws generally ended favorably, though the prognosis was by no means always mild. The prognosis was unfavorable in cases of chronic ulceration, of progressive serpiginous invasion of healthy skin, and where the tissues undermined as far as the ligaments, and even the bones. These phagedenic ulcers left horrible scars.

No disease was more contagious than yaws. When a child in a hut had been attacked all the other inhabitants contracted the disease if up to that time they had been free from it. The apparently great preference of the illness for the young was due to the fact that many adults had become immune by a previous attack. Children were, of course, more exposed to contagion than adults. In Cambodia and Laos it was quite common to see an infant being suckled by a woman whose breasts were covered with yaws, and when the child was to be weaned the mother put into its mouth pellets of rice which she had previously masticated. Up to the age of five or six the children of both sexes were naked, and their skin was covered with scratches and the ravages of mosquitos and scabies. Was it not possible that insects were the carriers of the disease? In certain countries the parents anticipated the inevitable attack of yaws by encouraging inoculation in every possible way! Among adults the disease was propagated by the chopsticks which were used instead of forks, the water pipe which was handed from mouth to mouth, and the sleeping mats which were common to all. The natives of Cambodia, Laos and Siam avoided all drugs during the first three months of the disease. The patient was then subjected to fumigations of mercury while wrapt in a mosquito net. Now and then he washed out his mouth with water or tea, which did not prevent his getting stomatitis and loose teeth. This treatment was remarkably successful for a time, though relapses usually occurred. Iodide of potassium in antisyphilitic doses had a good effect on yaws in two or three months.

**Spirochætæ in Yaws.**—Dr. Aldo Castellani of Colombo, Ceylon, contributed a paper on "The Presence of Spirochætæ in Two Cases of Ulcerated Parangi (Yaws)." In February, 1905, while examining some films made from the secretion of the ulcers in a case of parangi and stained by the Leishman-Romanowsky method, he noticed several extremely minute and almost invisible spirillum-like bodies. He did not attach much importance to this discovery at the time, because the spirilla were found together with huge numbers of other microorganisms, and were so faintly stained that their proper study could not be carried out. In June, 1905, having received from Prof. Schaudinn communication of the latter's discovery of spirochætæ in syphilis, and remembering the great similarity between parangi and syphilis, he at once began investigations to ascertain whether an identical or similar organism might not be present in yaws. He was able to examine four cases. Two of these, presenting only dry lesions, proved negative, but in the other two, who, in addition to dry lesions, presented some red fungoid, slightly secreting ulcerated excrescences, he found spirilla, which were, however, mixed with various kinds of bacteria. One of the positive cases he was able to examine many times. He was a Singhalese lad, ten years of age, who had never been out of Ceylon, and neither presented any other disease nor any signs of acquired or congenital syphilis. He was in the second stage of the disease. The skin of his hands and arms presented several patches of furfuraceous desquamation, the lower parts of the legs and the soles of the feet presented several fungoid, roundish, elevated, slightly secreting formations. The patient was undergoing mercurial treatment, and was improving. The spirochætæ found were always mixed with a prodigious number of bacteria in preparations from the surface of the lesions, but in preparations made after a thorough scraping of the superficial layers the bacteria were fewer, although the spirochætæ were not sensibly diminished. The spirochætæ were extremely thin. They stained very faintly, and, indeed, were often scarcely visible. However, they became fairly well stained when the Leishman alcoholic solution was allowed to act for five minutes and after admixture with distilled water for fifteen minutes. They generally take a purplish and occasionally a bluish tint. The spirochætæ measure on an average from fourteen to twenty microns in length, though short forms of from seven to ten microns are also met with. They are pointed at both extremities, and present a variable number of undulations. Two types might perhaps be distinguished—one with numerous small undulations, the other with fewer, broader, and more graceful waves. Here and there in the stained preparations a few shorter, thicker, and more deeply stained spirillum-like organisms, presenting one or two chromatin points within their cytoplasm, might be seen, as well as bacilli of various shapes and cocci innumerable. In fresh preparations (hanging drop) the spirochætæ, though extremely thin, could be distinguished from the many motile bacteria, on account of their peculiar movements, so well described by Schaudinn.

**Pellagra.**—Dr. Louis W. Sambon of London read a paper entitled "Remarks on the Geographical Distribution and Etiology of Pellagra." He said he believed pellagra was far more common in tropical and subtropical regions than was supposed. When we spoke of the geographical distribution of any disease, of course we meant our limited knowledge of its distribution. This was especially the case with regard to pellagra. Pellagra was still unrecognized in many of its endemic areas; its nervous symptoms, gastric derangements, and skin lesions being ascribed to other and separate diseases. A parallel example was that of kala-azar, a disease which was believed to be confined to the Assam valley until the discovery of its specific agent showed that it had a very wide distribution, not only in India, but throughout the tropical world. The recognition of pellagra was not always an easy matter for those who were not familiar with its symptoms and course. In Spain and Italy pellagra had been known for over a century and a half. In 1818 it was discovered in France, in 1833 in Roumania, and in 1839 in the Island of Corfu. More recently other endemic centers had been discovered in northern Portugal, Tyrol, Croatia, Bosnia, Benarabia, and Kherson. In Africa it was first recognized in 1847 by Pruner, who had studied the disease in Italy. Pruner's statements had been discredited by Hirsch and others, but recently Sandwith had shown that pellagra was very prevalent in Lower Egypt. The disease had been reported from Algeria and from the coast of the Red Sea. It had been encountered in South Africa and amongst the Kaffirs and Zulus. From Asia we had no definite information, but Dr. Ray had seen cases which agreed with the description of the disease, and Sandwith stated that Indian medical officers to whom he had shown photographs of pellagra patients admitted having seen similar skin lesions. In America pellagra was known to exist in Mexico. Dr. Low, who had had the opportunity of seeing cases of pellagra in Italy, had told him that he had recognized the disease in the West Indies, and a further inquiry had convinced Dr. Sambon that the disease was not uncommon in some of the West Indian Islands. Finally Dr. Neiret had reported it from New Caledonia. This proved that pellagra must be far more widely distributed than was generally believed, and, considering the grave importance of the disease, he thought it most urgent that medical men should learn to recognize it. In Italy pellagra was rightly considered to be one of the worst disease scourges of the country. Over 100,000 cases were known, and the disease was dreaded, not so much on account of its deadliness, but because of the indescribable wretchedness and suffering to which it gave rise during its slow, cruel course of many years. The disease was characterized by an erythema affecting the unclothed parts of the body most exposed to the sun, recurring each spring, and leaving behind a peculiar roughness and pigmentation of the skin which had given rise to the Italian name pellagra, meaning "rough skin." In its later stages it was characterized by progressive weakness, great emaciation, and by severe melancholia alternating with maniacal phases. The disease presented, moreover, very marked gastrointestinal symptoms—the tongue and palate lost their epithelium, and diarrhea was frequent, becoming unrestrainable and colliquative towards the end. The disease had been attributed to isolation, to bad water, to unsanitary dwellings, to poverty, to irritant oils, to garlic, and to maize. Most of these theories had been abandoned long ago. But the maize theory needed a serious scrutiny, because it was the theory now almost unanimously accepted. At first it was believed that maize lacked in nutritive principles; later it was surmised that it contained normally some toxic substance; finally it was agreed to ascribe the disease not to normal maize, but to decomposed maize, some holding that it was caused by certain toxic substances developed in the course of the decomposition of the grain under the influence of vegetable organisms; others that it was caused by the organisms themselves. Consequently, the various fungi and bacteria found on maize had all been incriminated in turn as the causative agents of pellagra. Dr. Sambon described the numerous researches, and pointed out that each investigator had claimed to have reproduced in animals true pellagra by the inoculation of the toxic substance or organism which he had isolated. These experiments had no better value than those by means of which Klebs and Tommasi-Crudeli sought to prove that their famous bacillus was the real cause of malaria. The most recent investigations were those of Di Petri, Ceni, and Besta, who incriminated certain varieties of *Aspergillus* and *Penicilium*. Their experiments were by no means convincing. These organisms were amongst our most common fungi; they could be found not only in diseased bread, but on the most heterogeneous media, such as fruit, cloth, jam, old boots. Their pathogenic properties were well known.

Dr. Sambon stated that he did not believe in the maize theory of pellagra any more than he believed in the current rice theory of beriberi. However, he was inclined to think

that, like the swamp in malaria, so maize and rice might represent necessary ecological factors in the natural history of the diseases with which they had been so long associated in popular belief, but, so far, he considered that no conclusive evidence had been adduced in favor of the maize theory of pellagra.

The maize theory of pellagra was chiefly an Italian theory. It had never found much favor in Spain, one of the principal seats of pellagra endemicity, where the disease was to this day regarded as a true "*morbus miseriæ*." It had been frequently remarked that the endemic areas of pellagra and the areas of maize culture were by no means overlapping, and, indeed, vast areas of maize cultivation had no pellagra, as, for example, the United States of America. On the other hand, it had been pointed out that pellagra had been observed in places in which maize was not cultivated and in people who had never used maize as an article of food. A comparative study of the distribution and prevalence of pellagra at different periods was decidedly unfavorable to the maize theory. In the days of Casal the Province of Oviedo in Spain was one of the chief centers of pellagra. In 1900 it was the province which suffered least from this cause, whilst the highest incidence of the disease occurred in the Province of Madrid. Now, no change whatsoever had taken place in the maize cultivation of the Province of Oviedo. The people there eat maize just as much as before, and no improvement had ever been adopted in the storage or preparation of maize. On the other hand, maize was hardly ever eaten in the Province of Madrid. Even more striking were the facts afforded by the spread of the disease in Italy. Pellagra was still very prevalent in the north of the peninsula, where maize formed the staple food of the peasants, but in recent years the disease had become far more prevalent in other provinces in which maize did not represent a principal article of food. It had also invaded the Campagna, the Puglie, Sicily, and Sardinia, thus proving that it had a tendency to spread slowly, but widely, and independently of maize cultivation. When once established in a region pellagra was very permanent, but its prevalence might vary considerably from year to year in connection with ecological conditions as yet undetermined. The general opinion was that pellagra had appeared soon after the introduction of maize into Europe, and that it had advanced *pari passu* with the extension of maize cultivation and the more general adoption of the new cereal as an article of food. This opinion had been repeated by almost every writer on the subject, but it was very questionable. One writer had stated that it would be difficult to find the term pellagra in books published before the beginning of the eighteenth century, and this was more than likely, because the term had been introduced by Frapolli in 1771, but the absence of the term pellagra did not mean the absence of the disease pellagra, and, indeed, Frapolli himself stated that the disease was already known at the end of the sixteenth century by the name of *Pellarella*.

An important fact was that pellagra did not attack indiscriminately all those who fed chiefly on maize, but picked out the field laborer. The poor who lived in towns, although they fed exactly in the same way as the field laborer, were not attacked. Towns in the very heart of intensly pellagrous areas showed that same remarkably immunity towards pellagra that was witnessed in the case of malaria. Possibly, therefore, it was in the maize field that the field laborer came in contact with the causal agent of the dread disease. Another important fact was the age incidency of the disease. Pellagra was chiefly a disease of middle age. The majority of cases occurred between twenty and sixty years of age. If maize or diseased maize were the cause of pellagra, children would be the principal sufferers, as in the case of ergotism. Pellagra did not attack all the members of a family at approximately the same time, as would be the case if the disease were due to some toxic food partaken of equally by all. Pellagra exhibited a marked seasonal incidence, and in those who had contracted the disease there was a pronounced recrudescence of all the symptoms each successive spring. These facts were incompatible with the maize theory. The characteristic erythema of the disease reappeared constantly every spring in the chronic pellagrous lunatics who spent several hours a day in the open air, notwithstanding their seclusion for years in asylums in which maize was not an article of diet.

Dr. Sambon thought that the unquestioning acceptance of the maize theory was most regrettable. The Italian Government was spending considerable sums of money for the elucidation and eradication of the disease, but so potent was the influence of the current theory that the investigations were limited to the study of the fauna and flora of stored maize. The Prefects of the various provinces attacked by the disease were directed to collect specimens of diseased maize and forward them to the laboratories of the Government Board of Health in Rome, where they were examined and experimented with. He regretted that the disease was not more fully investigated in the field and independently of any theory. If he were asked to suggest a new theory, merely as a working hypothesis, he would be inclined to draw attention to the many analogies between pellagra and some of the protozoal diseases which had been recently worked out. But his reason for bringing the subject before the meeting was not to propound a new theory, but to urge the necessity of a thorough investigation of this widely distributed disease.

## Surgical Suggestions.

**Toothache.**—H. B. Ray gives the following advice on the treatment of toothache by the practitioner: Toothache is essentially an inflammatory condition, and in 99 per cent. of the cases there is a cavity in the tooth. In those cases where there is a cavity, but no nerve exposure, the treatment is simple—apply a sedative and exclude the secretions of the mouth from the cavity; prompt relief will follow, and then advise the patient to visit a competent dentist. A very effective agent, and one always at hand, is the oil of cloves. It should be applied by saturating a pledget of cotton with the remedy and introducing it into the cavity with a toothpick or other pointed instrument; that being done, the secretions are kept out by filling the cavity with a little beeswax, a household remedy always at hand. The wax can be applied by warming over a lamp on the point of a knife and forcing into the cavity. The wax filling serves not only the purpose of keeping the secretions of the mouth out, but prevents thermal changes from affecting the nerve when hot and cold things are taken into the mouth.—*Southern Clinic.*

**Fistula in Ano.**—J. A. MacMillan says that the sterile gauze packing after fistula operations should be applied so as to serve the following purposes: (1.) To control hemorrhage and give relief during the first twenty-four hours by firm packing. (2.) To keep the sides of the wound separated during the second and third days by loose packing. (3.) To control exuberant granulations and maintain uniform healing, pressure from the gauze is applied as indicated, namely, firm packing where the granulations are exuberant, and very gentle pressure where they are frail. (4.) Besides these special purposes, the packing has the general function of drainage.—*Detroit Medical Journal.*

**Scalp Wounds.**—Bayard Holmes gives the following rules for the treatment of such injuries: (1.) Shave three inches about every scalp wound. (2.) Make every scalp wound a large incised scalp wound, so that it may be explored with the finger. (3.) Use no probe except the index finger. (4.) Trim with the scissors the edges of the scalp wound; the razor and the brush are not effective. (5.) Scrape out an old wound with a sharp spoon as a part of the mechanical removal of infection.—*Denver Medical Times.*

**The Umbilicus** is always difficult to disinfect in cleansing the skin before a laparotomy, but a measure much used in French clinics greatly adds to the efficiency of the sterilization. The fold of skin at the bottom of the depression is seized with a rather blunt Kocher's clamp, and is pulled upon so that the hollow becomes an elevation. All the folds are smoothed out in this way and thorough mechanical and chemical cleansing is possible.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 26, 1905:

| | Cases | Deaths |
|---|---|---|
| Measles | 115 | 6 |
| Diphtheria and Croup | 132 | 15 |
| Scarlet Fever | 54 | 2 |
| Smallpox | ..... | ..... |
| Chickenpox | 3 | ..... |
| Tuberculosis | 429 | 175 |
| Typhoid Fever | 329 | 20 |
| Cerebrospinal Meningitis | 14 | 15 |
| Typhus Fever | ..... | ..... |
| Yellow Fever | ..... | ..... |
| Cholera | ..... | ..... |
| Totals | 1,076 | 233 |

**The Therapeutics of Water Drinking and Some of Its Dangers.**—Eliza H. Root believes that the advice "to drink water copiously" often works serious harm. She believes that brain workers with too little muscular activity, or men who have excessive muscular activity without proper hygienic supervision, nearly always take a sufficient amount, if not an excessive quantity, of liquids in the form of tea, coffee, beer, milk, or water. The writer declares that the normal amount of water daily required is a mathematical calculation regulated by the sensation of thirst; a reduction of the body water by one per cent. produces thirst. Life can be sustained for a longer time when water is taken without food than when dry food is taken without water. It is said that six and a half pounds of water, holding in solution waste products, is excreted in twenty-four hours from the body weighing one hundred and sixty-five pounds; this will serve as an approximate guide to the necessary amount of water for daily ingestion. Many conditions must be considered before water drinking is prescribed, and its effects, so the writer believes, should be watched as carefully as those of any other therapeutic measure. If the amount of fluid is abnormally increased, it must be gotten rid of, oftentimes with deleterious effects on the system. The writer describes three cases in which excessive water drinking had become a habit in "nervous" women. She refers to the number of deaths that took place at a foreign water cure establishment for gout, and declares that excessive amounts of fluid can doubtless cause disease of the circulatory system and of the digestive tract, and in cases in which disease of either system exists the drinking of much water may be positively dangerous.—*The Woman's Medical Journal.*

**Rheumatoid Pains Following Injuries in High Altitudes.**—Charles F. Kieffer declares that rheumatism is so commonly associated in the minds of those who live in high altitudes with the low levels and damp atmosphere of the sea-board that they lose sight of its very great prevalence in their own regions. This disease, if not more prevalent in high, dry altitudes is at least equally so. The writer adds that it is not apparent just why this should be so unless it be that the climatic conditions favor the spread of a virulent, follicular tonsillitis which must be considered as a very common precursor of acute articular rheumatism. Special attention is paid in this article to the very frequent development of severe rheumatoid pains after injuries of the most varied nature. These pains may be out of all proportion to the severity of the original injury. They are often rebellious to treatment. They should not be confounded with the immediate painful reaction of joint, muscle, or aponeurotic structures to the injury done them, for they are strikingly rheumatic in character, and follow the injury at a considerable interval of time, while they have a distinct period of incubation. This disturbance commonly develops in from two weeks to two months after a Pott's fracture, for example, or a dislocation of the shoulder, or a sprain of the ankle joint. The patient experiences a severe crippling pain in the injured part, and sometimes in the neighboring articulations or muscles besides. The pain also is observed in all sorts of scar tissue, being noted in some instances in the scar of an abdominal incision. In a few cases this condition arises in very old injuries. Practically these cases yield to active antirheumatic treatment only. The pain disappears with systematic salicylate saturation. Probably the sodium salt is the most generally useful. Whenever possible the part should be put at rest. Soothing lotions may be applied. Heat is most beneficial, especially in the form of dry, superheated air, the old-fashioned ironing is very effective. Acupuncture is an excellent remedy in selected cases for pain in the lumbar muscles. The needle should be thrust laterally into the lumbar muscles for three or four inches. The resulting relief is most striking.—*Denver Medical Times.*

**Diagnosis of Lobar Pneumonia in the Child.**—M. G. Variot tells us that the classical symptoms of pneumonia in the adult, cough, bloody expectoration, physical signs of consolidation are often not marked in the infant. There is a rise of temperature, that has marked daily remissions and oscillations. The physical signs may not appear until the fifth or sixth day of the disease. Dyspnea and acceleration of respiration are far from constant. Cough is absent for several days. Expectoration is swallowed; when obtained it is not bloody. Hypothermia is the most constant symptom, accompanied in older children by pain in the abdomen. Defervescence takes place on the fifth to the seventh day. If the location of the pneumonia be central, and limited, the physical signs are not clear, and the diagnosis may be uncertain until the fall of temperature indicating resolution. The diagnosis has to be made from typhoid and from meningitis; the physical examination is rendered difficult by the irritability of the child, who cries when one wishes to percuss or auscultate. The signs of percussion appear earlier than those of auscultation. There is tympanic note over the affected lung, explicable by the vicarious emphysema. There is a slight dullness below the clavicle of the affected side. Bronchophony and crepitant râles are common. The x-ray gives a fair picture of the spot of hepatization when of any size. The diagnosis from bronchopneumonia is simple; in the latter the respiration is 60-80, cyanosis marked, physical signs are bilateral, percussion gives greater difference between the two sides, auscultation gives fine moist râles, with or without bronchi.—*Gazette des Hôpitaux.*

**Edema of the Lung.**—H. W. Syers draws our attention to edema of the lung as always secondary and a complication of other serious diseases. It is in no sense inflammatory, but purely mechanical. It is a pouring out of blood serum into the ultimate cells of the lungs. It is usually found to some degree in cases of death from all causes, except in sudden death in apparent health. It is most frequent at the bases, though any portion of the lungs may be involved. The two main causes are cardiac disease, with failing heart, and the renal disease with hypertrophy of the heart. In failing compensation it is an early sign of breaking down of the heart muscle. The venous circulation is over full and the serum is poured out into the lungs, giving signs such as crepitation, high-pitched percussion note, and diminished voice sound. In renal disease we have, instead of a low tension, a high one, with a hypertrophied heart. The signs are the same, but the edema is more apt to be in the upper portion of the lungs. It is an extremely serious condition. Edema is one of the most formidable complications of typhoid fever, occurring in the third or fourth week of the disease. In cases with feeble heart the treatment consists in digitalis, in combination with iodide of potash, to increase the contractile power of the ventricles. Another valuable procedure is venesection, or wet-cupping. In uremia the treatment is quite different; nitrate of amyl, nitroglycerin, and ether, to relieve tension and remove toxins. Iodides are valuable. In enteric fever stimulants and supportive remedies are in order.—*Treatment.*

### SCIATICA AND ITS TREATMENT.*

By WILLIAM M. LESZYNSKY, M.D.,
NEW YORK.

ATTENDING NEUROLOGIST TO THE LEBANON HOSPITAL; CONSULTING NEUROLOGIST TO THE MANHATTAN EYE AND EAR HOSPITAL AND THE HARLEM HOSPITAL.

Pain in the course of the sciatic nerve is of very common occurrence, but genuine sciatic neuralgia is extremely rare. Most of the cases assumed to be sciatic neuralgia are usually either a mild or a severe form of perineuritis or interstitial neuritis, and should be so designated, and others are symptomatic of interference with the nutrition of the nerve through some extrinsic lesion. Unfortunately, the indefinite term "sciatica" has been indiscriminately applied to all painful affections in the course of this nerve, regardless of its etiology or the nature of the pathological process. Nevertheless, for brevity's sake, and for lack of a better substitute, I shall use this traditional but euphonious term as descriptive of the affection under consideration. It will be appreciated later in the course of my remarks that sciatic pain is obviously a symptom in the vast majority of cases, and this point I wish to emphasize at the outset.

In my experience, the commonest causes of sciatica are exposure to cold, over-fatigue of the lower extremities, and pressure on the nerve from sitting habitually on a hard chair or bench, in susceptible individuals whose metabolic processes are impaired, be it in the form of rheumatism, gout, diabetes, or alcoholism. It often arises from injuries which may easily involve such a large vulnerable nerve, which in its course is mostly surrounded by muscle. It is thus affected by the strain of lifting heavy weights, after prolonged horseback or bicycle riding, long drives over rough roads, overwork at the treadle of sewing machines, etc. This will explain the frequent occurrence of this disease in males between the twentieth and sixtieth year, as they are more exposed to the above-mentioned causes than women.

The mildest and most favorable type of sciatica with which we have to deal is the following: A rheumatic patient, after sitting on a hard surface for a few hours at first notices numbness (from pressure) in the foot or leg, and later sciatic pain develops. Such patients are also subject to similar sensations in the ulnar distribution from pressure during sleep.

As a symptomatic manifestation, its correct interpretation is of paramount importance, as sciatic pain occurs in all diseases of neighboring organs that are associated with compression of the sciatic nerve or the sacral plexus. Tumors and inflammation within the pelvis or of the spinal meninges, vertebral caries, uterine disease, pressure of the pregnant uterus, injuries accompanying parturition, malignant disease of the rectum or its distension with hardened feces, internal hemorrhoids, aneurysm of the abdominal aorta, and sarcoma of the femur have all been recognized as the cause of sciatic pain.

Sciatica may result from a dislocation or fracture of the thigh, ischiadic hernia, neuroma, aneurysm of the popliteal artery, flatfoot, and even tight shoes.

While in some instances it is in all probability a local manifestation of a general toxemia, it is very rarely observed as a result of toxemia from lead or mercury. The same may be said of sciatic neuritis of syphilitic origin. Sciatic pain has often been noted as an accompaniment of gonorrheal urethritis and epididymitis, which is evidently a referred pain. It has also occurred in patients with malarial toxemia. Chronic interstitial nephritis and arteriosclerosis may also present a causal relation to sciatica.

Anemia, chlorosis, hysteria, and neurasthenia have much less influence in its production than in other forms of neuralgic pain. Climatic and atmospheric conditions are not to be underestimated. In the more pronounced forms, that are secondary to organic disease of adjacent structures, the affection should always be regarded as neuritis, for several or many signs of neural inflammation are invariably present.

In an individual case, the cause is often more difficult to determine than would at first appear. After observing a large number of cases, one discovers that no two cases are exactly the same in their origin or course.

For simplicity in classification they may be divided into two groups, according to the duration and the stage of development. In the first group are those which develop suddenly or very rapidly while in the second are those which develop slowly. Sciatica due to exposure to cold develops rapidly and often suddenly. Cases that develop slowly are often either symptomatic of intra-pelvic disease, or due to some form of external pressure, or are secondary to inflammation of adjacent structures.

The diagnosis of sciatic perineuritis is based upon the presence of pain or tenderness on pressure over the nerve trunk, which sometimes radiates to the foot or toes; pain elicited or increased by passive extension of the leg upon the thigh while the thigh is held at a right angle with the pelvis; and diminution or loss of the Achilles reflex. The absence of these symptoms leads at once to the assumption (which in nearly every case is confirmed by further examination) of either a very mild degree of perineuritis, or a symptomatic or reflected pain resulting from intrapelvic disease. However, the signs of neuritis vary in degree in every case just as the element of pain. In doubtful cases, particularly in women, pelvic and rectal examination are absolutely essential.

Degenerative neuritis (interstitial or parenchymatous), which is very rare and usually due to injury or growths directly involving the nerve, is attended by unmistakable phenomena in addition to pain, such as paresis or paralysis, atrophy, loss of the Achilles reflex, anesthesia, vasomotor disturbances, and loss

* Read before the Bronx Medical Society, April, 1905.

* In preparing this paper, I have not had the necessary time to review my records and classify the cases from an etiological standpoint. But a statistical report is not of much clinical value anyway, so that nothing has been lost by the omission.

of faradic irritability in the distribution of the sciatic nerve.

A man thirty years of age was dragged some distance under one of the cars of a freight train, which resulted in dislocation of the hip-joint and an extensive lacerated wound, dividing the trunk of the sciatic nerve. When seen a year later, the hip-joint was normal and the wound had completely healed, but there were pain, paralysis, atrophy, and anesthesia in the sciatic distribution, yet he was able to walk without assistance. He remained in the same condition for several years, and then passed from observation. This case is mentioned in order to recall the remarkable fact that even when the conductivity of the nerve is destroyed, whether from traumatism, growths, or degenerative neuritis, the patient is still able to walk, although all of the muscles supplied by the nerve are completely paralyzed. What a contrast, when from neuritis or injury of the anterior crural nerve, the patient's leg becomes absolutely useless for locomotion, owing to paresis or paralysis of the quadriceps group!

The sciatic nerve has also been involved in tumors, such as sarcomata, myxomata, and fibromata. The growths are usually sarcomatous, and spring entirely, as a rule, from within the nerve sheath, and, forming an infiltrating mass, ultimately destroy the nerve. Such patients have been treated unsuccessfully for sciatica for a long time, before the true nature of the trouble has manifested itself.

Lumbago, *i.e.* lumbar myositis, which is frequently accompanied by pains radiating towards the thigh, is sometimes mistaken for sciatica. Periostitis or osteomyelitis of the femur or tibia may also be confounded with sciatica, a fact often discovered later by the surgeon. Or the presence of foci of rheumatic myositis may induce a clinical picture resembling sciatica.

Mr. B. for several years visited the baths as Sharon and Richfield Springs, in order to be relieved of a supposed sciatica. I saw him for the first time in 1895, and his gait and the position of the limb did not correspond with that usually seen after a sciatica of several years' duration. After a careful examination, not a single symptom of involvement of the sciatic nerve could be found. However, a region was discovered over the femur which was painful and swollen. On exploratory operation, considerable periostitis with infiltration of surrounding tissues was evident. Surgical measures resulted in complete recovery in a few weeks.

Acute rheumatic inflammation of the hip-joint is not so likely to be mistaken for sciatica as the more chronic forms of coxitis, such as tubercular arthritis. Inflammatory affections of the sacro-iliac-synchondrosis are commonly mistaken for sciatica. The same may be said of osteoarthritis of the lumbosacral region, the pain being caused by involvement of the nerve roots in the inflammatory exudation along the vertebræ. Pain in the course of one or both sciatic nerves may be an early and premonitory symptom of tumor of the spinal cord. Hence, in all cases of sciatica of long standing, a search should be made for evidence of a possible neoplasm. When a growth or meningitic process involves the cauda equina, the pain is more likely to affect both sides. In this connection, let me call your attention to the necessity of distinguishing sciatic neuritis from the pains of tabes. In the latter, the pains are often bilateral and more or less periodical; they are momentary in duration, usually affecting small spots in different parts of the limbs, and are associated with other symptoms of tabes, such as loss of knee-jerks, etc. In uncomplicated sciatica the knee-jerks are always exaggerated.

At times, from overwork of the healthy extremity in unilateral sciatica, similar pain is developed on the other side. The uninitiated may be readily deceived in such a case, for it also happens that one side becomes affected shortly after the other in beginning disease of the cord and its meninges. Of course, the diagnosis of spinal cord disease is not based only upon the location of the pain, but upon its association with other phenomena.

A brief narration of a few unconventional cases selected from my records will, do doubt, prove interesting.

A man forty years of age had for a long time complained of unilateral sciatic pain. He was treated ineffectually for several months, when it was for the first time noticed that the great trochanter was slightly enlarged. This gradually increased, and it soon became evident that the pain was due to osteosarcoma of the femur. This ultimately extended to the pelvis and terminated fatally.

Mrs. F., thirty-five years of age. Left sciatica of one year's duration. I had her examined by a gynecologist, who reported everything normal, including the bladder and rectum. The pain was relieved by local treatment of the limb. In four months she was completely well. Two months later, metrorrhagia. Another examination revealed uterine fibroids, which continued to increase in size, the pain returning and resisting all treatment. Ultimately, on account of the repeated hemorrhage, she submitted to operation. The pains disappeared and have never returned. Seven years have elapsed since the operation.

Mr. L., twenty-five years of age, had vertebral caries during boyhood, and was under the care of the late Dr. Ketch for twelve years, and has always worn a brace. The carious process healed, leaving him with a pronounced kyphotic deformity. His general health remained satisfactory. He consulted me in the fall of 1898. For a few months previously there had been dull, heavy aching in both thighs, anteriorly and posteriorly. This soon disappeared. Several weeks later, gradual but rapid development of left sciatic neuritis extending to the foot. It was discovered, much to his surprise, that the trouble was due to pressure from the heavy steel spinal brace that he had been wearing many years. The removal of the brace and the adjustment of a new support was followed by rapid amelioration of the pain. After several months' treatment, he made a permanent recovery.

Mrs. S., thirty years of age. In the fourth month of pregnancy complained of sciatic pain, which was especially worse at night while in bed. The pain was very much less when standing or bending forward. She discovered that, lying partly on her abdomen and sidewise, she was able to sleep, but should she change this position the pain returned immediately. Post partum, the pains disappeared at once. In a subsequent pregnancy there was a repetition of the same conditions. This case represents a pure type of symptomatic neuralgia from intrapelvic pressure. No doubt, the obstetricians will tell us that such cases are quite common.

Mrs. W., twenty-eight years of age, gradually developed left sciatic neuritis. She was decidedly rheumatic, and had always suffered from constipation. She had been confined to her bed for five months. There was more or less myositis of the lumbar muscles, and she was unable to change her position in bed without extreme pain. Although no symptoms relating to the rectum other than the persistent constipation had been complained of, yet a large mass of internal hemorrhoids was discovered, and removed by clamp and cautery. This was followed by rapid improvement, and simplified the management

of the constipation. Systematic treatment resulted in complete recovery at the end of two months.

The risk of accepting the patient's own diagnosis, or basing one's conclusions on the patient's description of the pain, must be quite evident, yet this is done only too frequently, and further examination is commonly neglected. Of course, the location of the pain is usually established by the patient's own statement, although even this must be carefully analyzed. But the etiological diagnosis in an individual case is the predominant feature. In view of the multifarious conditions that may occasion sciatic pain, the discovery of the cause is often beset with difficulty, and in its accurate determination at times requires the cooperation of the neurologist, gynecologist, or surgeon.

In the management of patients with sciatica our first duty is to ascertain the cause, and, if possible, remove it. While this is often extremely difficult, and at times impossible, constitutional conditions should always receive appropriate attention. Haphazard or empirical therapeutics, without the indispensable preliminary examination, is deserving of all the condemnation it has received. It is hardly necessary to state that in those cases in which the cause is still operative and removable, the most brilliant and gratifying results are obtained. On the other hand, in the presence of malignant or irremediable organic disease, palliative measures seem to be our only hope.

Effective remedies are at our disposal, but their successful utilization depends upon their skilful selection and adaptation to the case in hand. In the acute cases, the relief of pain as soon as possible is a *sine qua non*. The patient must be kept at rest in bed, with or without fixation of the extremity by a long splint, according to indications. A hot, wet pack is then applied to the limb.

The ice-bag has not always been as servicable, although it is certainly of value in some cases. The lower bowel is then cleansed by enema, which is followed by hot saline irrigation (with a Kemp's tube) at a temperature of about 110°, or as hot as the patient can bear it, for thirty or forty minutes. I have resorted to this method of irrigation several times daily in a number of cases, and it has invariably been followed by great relief. When the pain is so severe that the patient will not tolerate any handling, it may be necessary at first to administer morphine or codeine, or a morphine or opium suppository. Calomel or castor oil should also be given, a very important feature in all of these cases being to keep the lower bowel free from accumulation as well as to eliminate toxic intestinal products. As the restlessness and pain are usually worse at night, much benefit and relief will be derived from the use of a morphine or opium suppository each night until the acute symptoms have subsided. Consequently, I have repeatedly known patients to arise the following morning and rest comfortably for several hours upon a lounge. There need be no hesitancy about this plan of administering opium in these cases, for, if one neglects to do this, and lets the patient go through a night of distress, he naturally becomes discouraged and despondent. Some diversity of opinion exists among writers as to the use of massage in acute cases. In my experience, it has proved in many instances a very valuable adjunct, but its value depends upon the skill and dexterity of the operator and the degree of sensitiveness of the patient.

As a rule, it is more applicable after the acute symptoms have subsided. If massage is done too vigorously the pain is increased; hence, the greatest delicacy of manipulation is essential. During the last two winters I have attended a number of physicians suffering from acute sciatic neuritis, and they have all testified as to the relief obtained by suitable massage. As soon as practicable, more active hydrotherapeutic measures should be instituted. Superficial linear cauterization with the Pacquelin along the course of the nerve trunk and over the sacral region is often remarkably efficacious in relieving the pain.

The continuous galvanic current has also proved serviceable in my hands at the end of the first week. Large electrodes should be used (4 by 6½ inches), the weight of the patient's body while in recumbency holding them in contact with the skin. One electrode is placed over the lumbosacral region and the other over the posterior surface of the thigh, and the latter changed to the popliteal space during the course of the application by a sliding motion without removing it from the skin. The polarity is immaterial. The seance should last from ten to fifteen minutes daily, or oftener, and the current strength as much as the patient can tolerate with comfort. Great care should be observed that the metallic surface of the electrodes is adequately protected, otherwise painful eschars will result which take a long time to heal, and materially interfere with the continuance of electrical treatment. Galvanism is of more value, however, in the mild, subacute, or chronic cases.

Mild cases may be treated by the application of hot water cloths, followed by massage and rectal irrigation. Such simple means will often suffice in effecting a cure. In some instances, the pain may be relieved by salipyrin, aspirin, or phenacetin. Most of the acute cases, under proper management and control, recover promptly, but with the probability of recurrence. Hence, systematic preventive measures should be followed for several months or longer.

In the subacute or chronic forms, the treatment is somewhat different, and, as a rule, very little can be expected from the use of drugs excepting as adjuvants. A modified form of "rest cure" is quite essential in many cases. The occupation and habits of the patient often require radical change, particularly in people whose vocation necessitates violent and active muscular exercise of the extremities. In those whose employment requires an almost continuous sitting position, we must not forget to instruct them to change their attitude from time to time, and to sit on a soft seat or air cushion in order to protect the nerve from pressure.

Daily massage with passive movements and regulated systematic exercises, together with occasional passive extension of the limb for the purpose of producing moderate stretching of the nerve and loosening any adhesions, are among the most reliable and efficient means at our command.

Judicious hydrotherapy in some form should never be neglected. In conjunction with the foregoing plan, more cures have been accomplished than by any other methods, always taking into consideration the general management. The local wet pack or the Scotch douche, or both, have proved most serviceable, although other hydriatric procedures have been recommended. The wet pack applied at night is a very excellent means for relieving the pain as well as influencing favorably the neuritic process. For this purpose, we may make use of one leg of a heavy pair of drawers, which is dipped in water at 65° F., and placed in position like a stocking. A roller bandage is then applied, so that the leg may be kept in a continuous perspiration all night. This is removed in the morning, and followed by a warm water ablution and massage, etc. The same procedure may be repeated during the day if necessary. After about ten or twelve packs much improvement often results.

In some chronic cases, static electricity either in the form of sparks or the static induced current, or the Faradic wire brush, have proved more or less efficacious as supplementary to other treatment. Blistering over the course of the nerve by the application of cantharidal collodion is also useful, and is much more elegant than the troublesome old-fashioned fly-blister. It will suffice to mention the use of acupuncture, methyl chloride, or carbonic acid spray, and the injection of cocaine or sterilized water into the nerve trunk, all of which have had their advocates, and at times afford temporary relief from pain.

Notwithstanding its historical interest, it would be a waste of time to enumerate the multiplicity of drugs that have been utilized for "better or worse" in this disease.

A certain percentage of patients with chronic sciatic neuritis have proved unamenable to treatment, it has seemed to me, because they have not submitted to any persistent or systematic plan, but, becoming discouraged, have resorted to desultory methods until the affliction has become intolerable. After going the rounds, and having "tried" this and that doctor, or this and that "treatment," they are anxious to have something new and radical done for their relief. Then the surgeon is asked to cut down and stretch the nerve, or to do a "bloodless stretching" by forcible extension. Unfortunately, neither of these operations are absolutely safe, for both have been followed by myelitis, and both have usually proved inefficacious, although some temporary improvement has ensued.

In long-standing and persistent cases, I should be in favor of exploratory operation for the purpose of exposing the nerve trunk, and incising its sheath and freeing it from any surrounding adhesions. This should be followed later by the methods heretofore described.

Aside from those cases in which the sciatica is only a symptom of severe bone disease, affections of the spinal cord, or pelvic tumors, etc., the prognosis is not always to be looked upon as unfavorable. The expectation as to recovery is better in young than in old persons, and in those in fair general health, than those with renal disease or diabetes. The more pronounced neuritic processes are not so rapidly amenable to treatment as the milder types, and one attack predisposes to a recurrence.

The plan of treatment must necessarily vary with each case. Measures that are curative in one case may be absolutely useless in others, although clinically, the conditions are apparently the same. While it must be admitted that some cases are exceedingly rebellious to ordinary methods, the attending physician will sooner or later come to the realization of the fact that, when the circumstances and surroundings of the patient do not permit of prolonged and systematic management at home, very little can be accomplished toward a cure outside of a well-conducted course in a hospital or sanatorium.

56 East Fifty-eighth Street.

**Diphtheria of Wounds.**—R. Balderi gives us the history of three operative cases seen in the orthopedic wards of Rome, in which the wounds became infected with diphtheria. When the wounds were opened, on account of rise of temperature and tumefaction, it was found that the surfaces were covered with a grayish-white membrane. Cultures from this membrane showed Klebs-Loeffler bacilli, and antidiphtheritic serum caused it to disappear, and the children recovered. He gives us the following conclusions; (1) Sterilization of all materials used in dressing wounds is most important. (2) Hospital gangrene is produced by the Loeffler bacillus combined with the pyogenes communis. (3) In every case of hospital gangrene Behring's serum should be used at once and repeated until cure results.—*Gazzetta Medica di Roma.*

## A SCIENTIFIC CLASSIFICATION OF THE METHODS OF MODIFYING COW'S MILK FOR INFANT FEEDING.

By GODFREY ROGER PISEK, M.D.,

NEW YORK.

PROFESSOR OF PEDIATRICS, UNIVERSITY OF VERMONT; ADJUNCT PROFESSOR OF PEDIATRICS, NEW YORK POST GRADUATE MEDICAL SCHOOL; ASSISTANT VISITING PHYSICIAN TO THE BABIES' WARDS, NEW YORK POST GRADUATE HOSPITAL.

From time to time various methods of modifying or adapting cow's milk for the use of infants have been brought forward and advocated by different authorities. Many of these methods differ widely in the principles involved, and to any one engaged in teaching the subject of infant feeding the problem which arises at the outset is: Which method shall be taught? Which principle is the correct one?

Only a few years ago surgery was in the hands of a few; to-day competent surgeons are found in almost every small town, because the principles of asepsis on which successful surgery depends are well and uniformly taught. Good infant feeders would be as well distributed as good surgeons if the principles of infant feeding were settled beyond dispute. It is time that a clear understanding of the principles involved in the various methods of feeding became general, and that these methods be used, or not used, on their merits, and with a distinct knowledge of their effects.

The student of to-day is laboratory trained, and the teacher must be able to *demonstrate* to his pupil the teachings concerning infant feeding. He will then be able to weigh the evidence presented, and later correctly interpret his clinical observations. Incidentally, the demonstrator may, and probably will, disprove some of the present accepted teachings.

The object of this paper is not to advance any particular method of feeding, but to classify the principles involved in all of the methods proposed, and also to show the effect of the use of these methods. The scientific principle applied in the method of any authority can then be readily ascertained. What will be stated below as facts are either self-evident truths or are capable of demonstration. Before attempting a classification, it will be helpful briefly to outline the peculiar processes of infantile digestion and development.

*The Infant.*—If one of the modern text-books on biology or zoology is studied, it will be found that after any species or class of animals is described, a special section is devoted to the peculiar changes of form and function that take place in the young during their development. It is certain that the works on infants of the future will consider them from the biological standpoint and in a similar manner.

Young suckling animals at birth are not like chickens when hatched, little adults which simply enlarge to become adults. They develop new functions during the suckling period, and are gradually changing both their form and functions until the natural period of weaning, after which growth consists principally of enlargement. The anatomy of a young mammal is not the same as that of the adult. Especially is this so in the case of the digestive tract. Teeth are absent and the stomach is not like that of the adult, or proportional quantities of the adult food could be eaten and digested. It is evident, therefore, that the physiology of adult life does not apply to developing animals, and that milk must be a food that is peculiarly suited to an undeveloped stomach or it would not be supplied. There must be something about milk that is different from ordinary food that makes it particularly suitable for the developing young.

It is well known that during the suckling period the digestive tract develops and changes in its functions, and that when weaning takes place in nature the young are fitted to digest food natural to the species. Aside from the colostrum of the first week after birth, milk has been supplied by the mother which has practically the same composition and properties during the whole lactation period. Here, then, is apparently a curious state of affairs. The stomach of the young animal, constantly growing stronger, and still being supplied with the food that was suitable for the very weak stomach of the first few weeks of life. This is contrary to all observations of how changes of structure and function are produced in nature. Organs and muscles are increased in size and strength by greater use and not by continually lessening their work.

As mother's milk does not undergo any change in character as the young develop, it should suggest itself that possibly as the stomach develops *it* changes the milk so as to make it suitable for its altered form and function. As a matter of fact, the stomach secretions *do* change the milk before it is digested, building it up into solid compounds or curds, whose character depends upon the kind of digestive juice that is secreted. Bearing in mind that organs have a special form to fit them for special functions, this action of the stomach should be looked upon as being a necessary part in the digestive process, and one not to be lightly ignored or perverted in artificial feeding. If the stomach never received any solid food until weaning, how poorly prepared it would be for this kind of nourishment! But if it had been having milk changed into a solid which gradually became more difficult of digestion as the digestive secretions became stronger, how easily the stomach could take care of solid food as it was gradually added to the diet! Instead of the solid food coming as a shock, it would be only a little more difficult of digestion than milk, and the stomach would hardly notice the change. A large factor in feeding is gradually changing the diet and avoiding sudden changes in the character of the food. It can be readily demonstrated by adding to milk digestive secretion of increasing strengths, that as the digestive juice becomes stronger and assumes the adult type the milk is altered and requires more digestive effort.

*Digestive Secretions.*—At birth the mammary glands secrete colostrum whose proteids are principally soluble. Colostrum is gradually displaced by milk which has its proteids, or a part, at least, in the form of casein combined with calcium or lime[5] which forms curds in the stomach. After the milk flow is established the character of the milk does not change to all intents and purposes. The stomach of the young animal first secretes rennet ferment, which changes the casein and lime compound into a paracasein compound[5] (junket curd), which is unaffected by pepsin.[6] When a small quantity of acid is secreted it combines with some of the lime of this paracasein compound and forms a *free paracasein*[5] curd that is digestible by pepsin. Free paracasein curd is denser than the precipitated paracasein curd in combination with lime, which is produced by rennet alone. In the presence of still more acid the free paracasein acts as a base which combines with the acid to form chloride of paracasein,[5] which is also digestible by pepsin. Thus it is that the stomach secretions may form three distinct *solid compounds* with the casein of the milk, having different forms and digestive properties, depending on the strength of the secretions. Milk, it will be seen then, is a peculiar food that changes its physical form upon contact with the digestive secretions before digestion commences, for the purpose of supplying the stomach with a solid food of increasing density. Each milk obtained from a different species of animals will form a curd peculiar to itself. As the stomachs of young animals imperceptibly pass into the form and develop functions of the adult stomach while digesting mother's milk, it is evident that the mother's milk must be digested very much as the maternal solid food is digested. As the stomachs of animals show such marked differences of form and methods of digesting food, it is not at all surprising that the milks of animals with widely differing methods of digestion should show wide differences in properties. What else could be expected? The problem of the infant feeder in modifying milk then is like that of the dressmaker in making over an old-style dress. It is not like making up a piece of new goods. A great deal of ingenuity often must be employed to make a fit, but many of the methods of feeding pay no attention to either style or fit.

With this knowledge of the constructive effects of the digestive secretions on milk, it will be easy to grasp the following classification of methods of modifying milk:

*Classification of Methods of Modifying Cow's Milk.—Group 1. Methods that affect only the quantitative composition of cow's milk:* (*a*) Simple dilution with water; (*b*) dilution plus fat plus sugar; (*c*) removal of a portion of the casein (whey and cream mixtures).

*Group 2. Methods that prevent or alter the formation of curds in the stomach by inhibiting rennet action:* (*a*) Addition of lime water until slightly alkaline; (*b*) addition of carbonate of potassium until slightly alkaline; (*c*) addition of borax until slightly alkaline.

*Group 3. Methods that prevent or alter the formation of curds in the stomach by inhibiting rennet action, and also neutralize the acid of the stomach:* (*a*) Addition of 1 to 2 grs. bicarbonate of soda to the ounce of food; (*b*) addition of syrup of lime; (*c*) addition of magnesium hydrate.

*Group 4. Methods in which acids precipitate the casein and prevent the formation of rennet curds:* (*a*) Buttermilk feeding; (*b*) kumyss feeding; (*c*) matzoon feeding; (*d*) addition of dilute hydrochloric acid.

*Group 5. Methods that profoundly alter the character of the milk:* (a) Peptonizing milk; (*b*) addition of citrate of ammonium, 1 to 2 grs. to the ounce of milk; (*c*) addition of citrate of potassium, 1 to 2 grs. to the ounce of milk; (*d*) addition of citrate of sodium, 1 to 2 grs. to the ounce of milk; (*e*) addition of oxalate of ammonium, ½ to 1 gr. to the ounce of milk; (*f*) addition of oxalate of potassium, ½ to 1 gr. to the ounce of milk; (*g*) addition of oxalate of sodium, ½ to 1 gr. to the ounce of milk.

*Group 6. Methods that indirectly alter the milk:* (*a*) Scalding or boiling; (*b*) pasteurization; (*c*) sterilization; (*d*) condensed milk; (*e*) evaporated creams.

*Group 7. Methods that mechanically alter the curds of milk without affecting the action of the digestive secretions:* (*a*) Dilution with plain gruels; (*b*) dilution with digested or dextrinized gruels.

*Detailed Study of the Various Groups.—Group 1. Methods that affect the quantitative composition of milk:* The food of animals is subdivided into proteid, mineral matter and water, forming the blood and tissue builders, and fats and carbohydrates, forming the energy foods. These food elements are in all complete foods in one form or another, and, of course, in milk. The proportions in which they exist in milk are in direct relation to the rapidity of growth of the young animal, rapidly grow-

ing animals, naturally needing more of the blood and tissue building elements than slowly growing animals. It may safely be inferred that to insure proper growth and development, the infant needs as much tissue and energy foods as are found in human milk. They are supplied in human and cow's milk in about the following proportions:

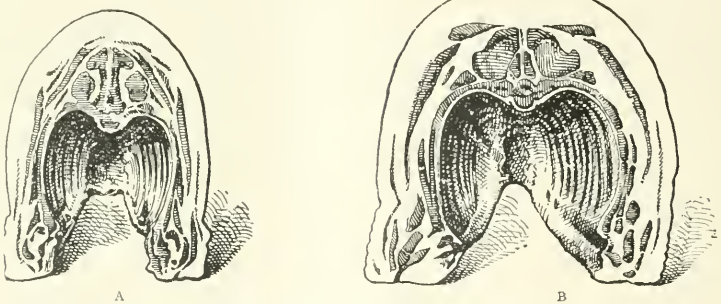
| | TISSUE BUILDERS. | | ENERGY FOODS. | |
|---|---|---|---|---|
| | Proteids. | Mineral Matter. | Fats. | Carbohydrates. |
| Cow's milk | 3.00–4.00% | .70–.80% | 3–5% | 4–5% |
| Human milk | 1.25–1.75% | .20–.25% | 3–5% | 6–7% |

The energy foods exist in cow's milk in about the same quantities as in human milk, but the tissue building foods are in larger amounts in cow's milk, as the calf grows more rapidly than the infant. It is the proteid of the cow's milk that forms the curds in the stomach, and to reduce the quantity of the curd the milk is diluted. This is often done as a clinical measure without any scientific reason.

When milk of the cow is diluted to reduce the addition of fat or cream and sugar. As any excess of energy foods is converted into body fat, it is found that an infant fed liberal quantities of sugar and moderate amounts of fat will gain rapidly in weight and apparently grow, even if the quantity of proteid is very low. Thus gain in weight may be made even if the infant is receiving a much smaller quantity of proteid than is found in human milk, as is seen in condensed milk feeding:

| | TISSUE FOODS. | | ENERGY FOODS. | |
|---|---|---|---|---|
| | Proteids. | Mineral Matter. | Fats. | Carbohydrates. |
| Condensed milk. | | | | |
| Diluted 15 times | 0.48% | 0.12% | 0.56% | 3.60% |
| " 10 " | 0.72% | 0.18% | 0.84% | 5.40% |
| " 7½ " | 0.96% | 0.24% | 1.12% | 7.20% |
| Human milk | 1.25–1.75% | .20–.25% | 3.00–5.00% | 6.00–7.00% |

Since a large part of the difficulty in feeding infants with cow's milk lies in the inability of the infants to digest the proteid or curd of the milk, and as apparent growth can be made on fats and sugars, it is taught that the quantity of proteid in the in-



A B

Section of two pigs from the same litter; A, fed on low proteids; B, fed on high proteids.

| At Beginning of Experiment. | | | Comparative Results at End of Experiment. | | | | | |
|---|---|---|---|---|---|---|---|---|
| | Age. | Weight. | Diet. | Weight. | Wt. of Blood. | Wt. of Liver. | Wt. of Spleen. | Wt. of Heart. | Wt. of Kidneys | Length of Body. |
| A.—100 days. | 50 lbs. | Low proteid. | 130 lbs. | 3.5 lbs. | 2.8 lbs. | .2 lbs. | .5 lbs. | 4 ozs. | 37.5 in. |
| B.—100 days. | 52 lbs. | High proteid. | 211 lbs. | 7.8 lbs. | 3.6 lbs. | .2 lbs. | .6 lbs. | 12 ozs | 40. in. |

quantity of proteid, the energy foods—fats and carbohydrates—are reduced to below the quantities supplied in breast milk, and which are necessary for the infant, as is shown in the following table:

| | TISSUE BUILDERS. | | ENERGY FOODS. | |
|---|---|---|---|---|
| | Proteids. | Mineral Salts. | Fats. | Carbohydrates. |
| Human milk | 1.25–1.75% | .20–.25% | 3.00–5.00% | 4.00–5.00% |
| Cow's milk— | | | | |
| Diluted to ½ | .75–1.00% | .18–.20% | .75–1.25% | 1.00–1.25% |
| " to ⅓ | 1.00–1.33% | .23–.27% | 1.00–1.70% | 1.33–1.70% |
| " to ½ | 1.50–2.00% | .35–.40% | 1.50–2.50% | 2.00–2.50% |

The effect of this method is that proteid which is difficult of digestion, and which should be used for growth, is called upon to supply the energy that is needed by the infant and is used as fuel. The result is that the infant does not gain in weight and strength as it should, even when it is taking as much proteid as is supplied in human milk. When fat or cream and sugar are added to diluted cow's milk, they can supply energy and allow the proteid to be used in making new blood and tissue.

| | TISSUE BUILDERS. | | ENERGY FOODS. | |
|---|---|---|---|---|
| | Proteids. | Mineral Salts. | Fats. | Carbohydrates. |
| Cow's milk 1 + water 2 = | 1.00–1.33% | .23–.27% | 1.00–1.70% | 1.33–1.70% |
| Add cream and Sugar = | ..... | ..... | 2.00–2.30% | 4.67–5.30% |
| Milk + water + cream + sugar = | 1.00–1.33% | .23–.27% | 3.00–5.00% | 6.00–7.00% |
| Human milk | 1.25–1.75% | .20–.25% | 3.00–5.00% | 6.00–7.00% |

In this way growth can be made on a dilution of milk that would be a starvation diet without the fant's food should be greatly reduced, as in the following formulas, keeping up the quantity of energy food to a high point at the same time:

| | TISSUE FOODS. | | ENERGY FOODS. | |
|---|---|---|---|---|
| | Proteids. | Mineral Salts. | Fats. | Carbohydrates. |
| | 0.25% | .04% | 3.00–4.00% | 6.00–7.00% |
| | 0.50% | .08% | 3.00–4.00% | 6.00–7.00% |
| | 0.75% | .12% | 3.00–4.00% | 6.00–7.00% |
| | 1.00% | .16% | 3.00–4.00% | 6.00–7.00% |
| Human milk | 1.25–1.75% | .20–.25% | 3.00–5.00% | 6.00–7.00% |

As a large excess of energy foods above the actual requirements of the infant is generally fed with the low proteid, this is converted into body fat and the infant gains in weight; it is supposed to be growing, but in reality it is being stunted and deprived of its natural rights, for true growth cannot take place without sufficient supply of proteid and mineral matter for the bones. Fats and carbohydrates are not converted into vital tissue, and an infant receiving only one half as much tissue food as a breast-fed baby cannot become as well developed. The laying on of fat masks the lack of tissue development. The illustration and comparative weights from animals fed in this manner[1] show the effect on the body development of feeding small quantities of tissue food with large quantities of energy foods. All of the organs are stunted, the chest is contracted, and there is a small amount of blood in the body. The bones also are weak in animals fed low proteid.[2]

Such nutrition experiments have been conducted continuously for about ten years with the same re-

sults everywhere.[2] The following is the average of seven sets of litter brothers fed high and low proteids[1]:

AVERAGE OF SEVEN LITTER PAIRS OF ANIMALS.

| | Weight. | Wt. of Blood. | Wt. of Spleen. | Wt. of Liver. | Wt. of Heart. | Wt. of Kidneys | Length of Body. |
|---|---|---|---|---|---|---|---|
| Low Proteid Diet. . . . . | 172.5 lbs. | 4.5 lbs. | .18 lbs. | 2.6 lbs. | .46 lbs. | 5.71 ozs. | 38.4 in. |
| High Proteid Diet. . . . . | 208.3 lbs. | 6.02 lbs. | .25 lbs. | 3.26 lbs. | .50 lbs. | 10.30 ozs. | 39.0 in. |

W. A. Henry[2] gives the following comparative results of high and low proteid feeding, reduced to a basis of equal weight:—

| | Blood per 100 lbs. Weight. | Liver per 100 lbs Weight. | Muscular Tissue. | Strength of Bone. |
|---|---|---|---|---|
| Low proteid diet . . . . . | 36.8 ozs. | 31.9 ozs. | 1.00 | 380 |
| High proteid diet. . . . . | 51.2 ozs. | 48.4 ozs. | 1.33 | 503 |

*Whey Feeding.*—As the curds of cow's milk which has been diluted often causes indigestion, it has been proposed to remove the casein from which the curd is formed by the rennet ferment of the infant's stomach and feed the remaining soluble whey with more or less quantities of the casein. As the casein was placed in milk for the specific purpose of supplying the solid food for the growing stomach, its removal, except temporarily, cannot be looked upon as a rational method of preparing foods.

*Group 2. Methods that inhibit rennet action and formation of curds:* It has been generally believed that one of the great differences between human milk and cow's milk is that cow's milk is acid and human milk is alkaline in reaction and that some alkali should be added to cow's milk to make it like human milk. When both milks are tested with litmus paper, a great variety of results may be obtained.[3] Varying grades of litmus paper will show the same milks to have all kinds of reactions, so that a more delicate reagent—phenolphthalein—is used to determine the reaction of milks. With this test it is found that both kinds are decidedly acid.[3]

"It may be well in this connection to call attention to the inaccuracy involved in attributing the acidity of milk or cream to lactic acid alone. The usual method of determining acidity in milk or cream is to titrate a given amount of milk with a standardized solution of fixed alkali, using phenolphthalein as indicator, the alkali being added to the milk until a fairly permanent pink color appears. Lactic acid is not the only compound in milk that neutralizes alkali. It is well known that strictly fresh milk which contains no lactic acid, neutralizes an appreciable amount of alkali. The compounds in fresh milk or cream that have the power of neutralizing alkali are the following: (1) Calcium casein (milk-casein); (2) acid phosphates and citrates, and (3) carbon dioxide. Of these, the calcium casein and acid phosphate appear to be the most prominent in neutralizing alkali" (Van Slyke and Hart).[4]

Human milk requires 10 to 20 per cent. of lime water to neutralize it, and cow's milk 50 to 80 per cent.[3] The alkali combines with the casein and forms a definite compound called basic calcium casein.[5] This product, which is neutral to phenolphthalein, will not be changed into a curd by the rennet ferment of the stomach even in the presence of soluble lime salts, as will the natural casein of fresh milk.[5]

Many of the authorities state that 5 per cent. of lime water is sufficient to add to cow's milk to give it the same reaction as breast milk, but further recommend that the same percentage should be added to the infant's food, no matter how much the milk it contains is diluted. Also that for young infants whose food contains very small quantities of milk, 10 per cent. of limewater should be added to the food. In reality this makes the quantity of limewater added to the *milk* of the food as high as 200 per cent., which would more than convert the casein into basic calcium casein, and thus prevent formation of rennet curds. Southworth has recently published a table showing how completely the theory of adding limewater is abandoned in practice.[6]

SOUTHWORTH'S TABLE (Condensed).

| According to Theory Whole milk + 5% lime water is alkaline. | | | According to Practice 5% lime water is added to diluted milk or food. | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | Food + 5% Lime Water. | | | | Food + 10% Lime Water. | | | | | |
| Alkaline Milk. | + Water = Food. | % Lime Water in Alkal'n Food. | % Lime Water in Milk. | Lime Milk. | + Water + Water = Food. | % Lime Water in food | % Lime Water in milk | Milk. | Lime Water. | Water. Food. | % Lime Water in food. | % Lime Water in milk. |
| 1 oz. | + 19 ozs. = 20 ozs. | 0.25% | 5.00% | 1 oz. | + 1 oz. + 18 ozs. = 20 ozs. | 5% | 100 % | 1 oz. | + 2 ozs. + 17 ozs. = 20 ozs. | | 10% | 200% |
| 2 ozs. | + 18 ozs. = 20 ozs. | 0.50% | 5.00% | 2 ozs. | + 1 oz. + 17 ozs. = 20 ozs. | 5% | 50 % | 2 ozs. | + 2 ozs. + 16 ozs. = 20 ozs. | | 10% | 100% |
| 3 ozs. | + 17 ozs. = 20 ozs. | 0.75% | 5.00% | 3 ozs. | + 1 oz. + 16 ozs. = 20 ozs. | 5% | 33⅓ % | 3 ozs. | + 2 ozs. + 15 ozs. = 20 ozs. | | 10% | 75% |
| 4 ozs. | + 16 ozs. = 20 ozs. | 1.00% | 5.00% | 4 ozs. | + 1 oz. + 15 ozs. = 20 ozs. | 5% | 25 % | 4 ozs. | + 2 ozs. + 14 ozs. = 20 ozs. | | 10% | 50% |
| 5 ozs. | + 15 ozs. = 20 ozs. | 1.25% | 5.00% | 5 ozs. | + 1 oz. + 14 ozs. = 20 ozs. | 5% | 20 % | 5 ozs. | + 2 ozs. + 13 ozs. = 20 ozs. | | 10% | 40% |
| 6 ozs. | + 14 ozs. = 20 ozs. | 1.50% | 5.00% | 6 ozs. | + 1 oz. + 13 ozs. = 20 ozs. | 5% | 16⅔ % | 6 ozs | + 2 ozs. + 12 ozs. = 20 ozs. | | 10% | 33⅓% |
| 7 ozs. | + 13 ozs. = 20 ozs. | 1.75% | 5.00% | 7 ozs. | + 1 oz. + 12 ozs. = 20 ozs. | 5% | 14 % | 7 ozs. | + 2 ozs. + 11 ozs. = 20 ozs. | | 10% | 28% |
| 8 ozs. | + 12 ozs. = 20 ozs. | 2.00% | 5.00% | 8 ozs. | + 1 oz. + 11 ozs. = 20 ozs. | 5% | 12½ % | 8 ozs. | + 2 ozs. + 10 ozs. = 20 ozs. | | 10% | 25% |
| 9 ozs. | + 11 ozs. = 20 ozs. | 2.25% | 5.00% | 9 ozs. | + 1 oz. + 10 ozs. = 20 ozs. | 5% | 11 % | 9 ozs. | + 2 ozs. + 9 ozs. = 20 ozs. | | 10% | 22% |
| 10 ozs. | + 10 ozs. = 20 ozs. | 2.50% | 5.00% | 10 ozs. | + 1 oz. + 9 ozs. = 20 ozs. | 5% | 10 % | 10 ozs. | + 2 ozs. + 8 ozs. = 20 ozs. | | 10% | 20% |
| 20 ozs. | + . . . . = 20 ozs. | 5.00% | 5.00% | 19 ozs. | + 1 oz. + . . . . . = 20 ozs. | 5% | 5 % | 18 ozs. | + 2 ozs. + . . . . . = 20 ozs. | | 10% | 10% |

Any alkali which will render milk neutral or faintly alkaline to phenolphthalein will prevent the action of the rennet forming curds and explains the effect of the addition of small quantities of carbonate of potassium or borax to milk as well as lime water, and part of the effect of adding bicarbonate of soda. The effect of alkaline additions to milk, then, is that of retarding the action of the infant's gastric secretions.

*Group 3. Methods that retard rennet action and neutralize the acid of the stomach:* In the previous group only enough alkali is generally added to convert the casein of the cow's milk into basic compounds which will not form curds with the rennet ferment in the stomach. When a sufficient quantity of acid is secreted to combine with the alkali, the milk is restored to its natural state and it will then form a curd.

In group 3, however, not only enough alkali or antacid is added to form basic compounds with the casein and so prevent the action of the rennet in forming curds, but enough is added to neutralize any acid that may be secreted which would restore to the milk its curding properties. All gastric digestion is thus prevented.

It is stated that the addition of one to two grains of bicarbonate of soda to each ounce of food is sufficient to neutralize the acidity of the cow's milk. The following table, also from Southworth,[6] shows how

much bicarbonate of soda to the ounce of milk is given when this plan is followed:

TABLE

Showing quantity of bicarbonate of soda added to each ounce of milk in a 20-oz. mixture when 1 to 2 grains are added to each ounce of food.—(Southworth.)

| Milk + | Water + | Bicarb. Soda | = Food. | No. Grs. of Bicarb. Soda to each oz. of Food. | No. of Grs. Bicarb. Soda to each oz. of Milk. |
|---|---|---|---|---|---|
| 1 ozs. | + 19 ozs. | + 20–40 grs. | = 20 ozs. | 1–2 | 20–40 |
| 2 ozs. | + 18 ozs. | + 20–40 grs. | = 20 ozs. | 1–2 | 10–20 |
| 3 ozs. | + 17 ozs. | + 20–40 grs. | = 20 ozs. | 1–2 | 6⅔–13 |
| 4 ozs. | + 16 ozs. | + 20–40 grs. | = 20 ozs. | 1–2 | 5–10 |
| 5 ozs. | + 15 ozs. | + 20–40 grs. | = 20 ozs. | 1–2 | 4–8 |
| 6 ozs. | + 14 ozs. | + 20–40 grs. | = 20 ozs. | 1–2 | 3⅓–7 |
| 7 ozs. | + 13 ozs. | + 20–40 grs. | = 20 ozs. | 1–2 | 3–6 |
| 8 ozs. | + 12 ozs. | + 20–40 grs. | = 20 ozs. | 1–2 | 2½–5 |
| 9 ozs. | + 11 ozs. | + 20–40 grs. | = 20 ozs. | 1–2 | 2⅓–4½ |
| 10 ozs. | + 10 ozs. | + 20–40 grs. | = 20 ozs. | 1–2 | 2–4 |
| 20 ozs. | + | 20–40 grs. | = 20 ozs. | 1–2 | 1–2 |

It will be noticed that in mixtures in which milk is moderately diluted five to ten grains bicarbonate of soda are added to each ounce of milk in the food, while in highly diluted food twenty to forty grains to the ounce of milk are given. A twenty ounce mixture, one-fifth milk, would contain twenty to forty grains of bicarbonate of soda and four ounces of milk. Four ounces of *sour* milk are neutralized by about fifteen grains of bicarbonate of soda, so in this case there is added, ostensibly to overcome the acidity of *fresh* milk, a great deal more than would be needed to neutralize the milk if sour. As the milk is not sour the bicarbonate of soda is not used as an antacid in the milk, but remains unchanged and passes into the infant's stomach ready to neutralize its acid and thus prevent gastric digestion. The milk remains fluid and can easily pass into the intestine.

The following table shows how much gastric juice of the adult containing 0.2 per cent. hydrochloric acid is neutralized by different quantities of lime water and bicarbonate of soda:

| Ounces Food | | Ounces Gastric Juice |
|---|---|---|
| 20 | 5–10% lime water neutralizes | 0.8–1.6 |
| | 1–2 grs. bicarb. soda to oz. neutralize | 10.0–20.0 |
| 30 | 5–10% lime water neutralizes | 1.2–2.4 |
| | 1–2 grs. bicarb. soda to oz. neutralize | 15.0–30.0 |
| 40 | 5–10% lime water neutralizes | 1.6–3.2 |
| | 1–2 grs. bicarb. soda to oz. neutralizes | 20.0–40.0 |
| 50 | 5–10% lime water neutralizes | 2.0–4.0 |
| | 1–2 grs. bicarb. soda to oz. neutralizes | 25.0–50.0 |

Syrup of lime and magnesia hydrate are alkaline, and also neutralize considerable acid.

Experiments on animals have shown that the continuous addition of antacid to their food prevents their assimilating food properly and retards development.[7]

*Group 4. Methods which precipitate casein by acids:* When acids are added to cow's milk they first combine with the lime of the calcium casein and liberate free casein; if sufficient acid is present it combines with the free casein and forms an insoluble precipitate like the curd of sour milk.[8,5] The rennet ferment will not form a curd with the precipitated casein of milk, and as this is finely divided and exposes a very large surface to the digestive juices it is digested by adults with greater ease[8] than the solid curds formed from fresh milk by rennet.

In making buttermilk, kumyss or matzoon, lactic acid bacteria develops in the fresh milk, and as they grow produce acid which combines with the casein and forms lactate of casein which is seen as fine flecks in the milk.

The addition of diluted hydrochloric acid to fresh milk produces a separation of chloride of casein.[8] Other acids also produce a similar effect.

*Group 5. Methods that profoundly alter the character of the milk:* As the curdling of milk by rennet in the stomach will not take place in the absence of a soluble salt of calcium or lime, any addition that will render the calcium of the milk insoluble will prevent the formation of curds. The addition of citrate and oxalate of ammonium, potassium, or sodium, causes a combination of the lime with the citric or oxalic acid; and of the casein with the ammonium, potassium, or sodium.[10] No rennet curd will form in milk so treated. The milk remains fluid. Adding lime water to milk so changes the casein that a soluble salt of lime has no effect.[5] Lime water does not have the effect of a soluble lime salt.

Adding peptonizing powder to milk, which contains bicarbonate of soda, changes the casein into soluble forms and also neutralizes the acid of the stomach.

*Group 6. Methods that indirectly alter the milk:* When milk is heated to the boiling point for any length of time it is so altered that the rennet ferment will not form a curd even after acid is added. This can readily be demonstrated by using the unsweetened condensed milks or the so-called evaporated creams after diluting them to approximate whole milk in composition, and adding first rennet, and then acid. A control with fresh milk should be used for comparison. Pasteurized milk is also more slowly acted upon by the rennet than fresh milk,[9] but the addition of enough acid to produce a soluble salt of lime causes typical rennet curds to form. Pasteurizing indirectly retards the curdling by rennet by destroying lactic bacteria which would produce acid, and thus accelerate the action of the rennet by combining with some of the lime of the milk and thus precipitating the curd.

*Group 7. Methods that mechanically alter the curds:* When milk is diluted with a thin gruel made of a cereal the gelatinized starch of the gruel makes the curd of the milk softer and more easily digested. Its action is almost entirely mechanical. If the milk is diluted with a digested or dextrinized gruel the mechanical effect is produced by the flocculent proteid of the gruel which also adds to the nutritive value of the food. It has recently been shown that the proteid of these gruels is often better digested than the proteid of milk.[11] A comparison of the nutritive values[12] of starch gruels and digested gruels is given below:

| | Prtoteids. | Carbohydrates. |
|---|---|---|
| Barley water or gruel (1 oz. to qt.) | 105% | 2.003 (starch.) |
| Digested barley gruel (2 ozs. to qt.) | 300% | 4.186 (no starch) |

A study of the above classification makes it evident that all methods of modifying cow's milk are based upon a rearrangement of the tissue building and energy food elements it contains, and interfering by chemical and mechanical means with the normal curding of the milk in the infant's stomach.

The practitioner must bear in mind the principles and apply them as indicated, to the individual case in hand, and remember that a method that may appear to give brilliant results with a sick infant may result in disaster if indefinitely continued.

The normal healthy infant must be fed quite differently from the child with a disordered or diseased digestive tract, and it is hoped that this paper will be an aid in ordering feedings for temporary or continued use. Too much of the present day feeding follows the plan of giving an analgesic and, finding the symptoms alleviated, allowing the patient to keep on with the remedy. The infant's digestive disturbances having been overcome, the feedings should be so ordered that grave constitutional diseases due to perverted functions shall not develop.

## KERNIG'S SIGN AND ITS PATHOGENESIS.

BY G. B. HASSIN, M.D.,

CHICAGO.

AT a medical meeting in St. Petersburg, Russia, September 21, 1882, Dr. Kernig briefly reported his first observations made during the years 1880-1882. on what is now commonly known as Kernig's sign.[1] The first description of the latter with report of clinical observations was made by Kernig in 1884. The description as given by this author was so complete that nothing has been added to it by later writers.

"In the majority of cases," says Kernig, "patients suffering from any form of meningitis (tuberculous, cerebrospinal) do not manifest contractures while lying, although there may be rigidity of the neck and back. There is absent extension—or flexion—contracture in both upper and lower limbs. If the patient be ordered to extend the limb which he had accidentally flexed, he does it readily and freely. But, *if the patient is sitting on the edge of the bed, so that his legs hang down,* then the rigidity of the neck and back is more marked and *flexion contracture sets in in the knee joints,* and occasionally also in the elbow joints. *One succeeds in extending the knee of the sitting patient only to the angle of* 135° and, if the phenomenon is very marked, *only to* 90°."

This sign, in Kernig's opinion, may confirm the diagnosis of cerebrospinal meningitis, if there is any suspicion of this disease, and may call the physician's attention to the latter, if there be absent any symptoms of meningitis. As soon as the patient changes the sitting posture for a dorsal or standing one, this phenomenon disappears. Kernig could also produce his sign in a reclining patient by flexing the thigh upon the body and the leg to the thigh at right angle.[2] Kernig's observations were confirmed by Bull of Christiana,[3] Friis of Copenhagen,[4] and Blümm of Germany,[5] but soon were forgotten and his sign was not even mentioned in the textbooks.

In 1898 Prof. Netter of Paris, France, on account of an epidemic of cerebrospinal meningitis, examined all his cases for Kernig's sign, studied this phenomenon very carefully, and pointed out its diagnostic value in a brilliant article published in *La Semaine Médicale.*[6] Netter's paper attracted great attention to Kernig's sign, and was followed by a number of serious and competent papers concerning this question. It was shown that Kernig's sign, indeed, appears more or less constantly in meningitis, but it cannot be looked upon as pathognomonic, because it is sometimes met with in other diseases, like sciatica, typhoid fever, and some affections of the central nervous system, such as cerebral hemorrhage, tumors of the brain, or tabes.

Carrière,[7] for instance, found Kernig's sign positive in 44 per cent. of cases of typhoid fever in children; in twenty-two of fifty cases the sign was marked, and in seven it was slightly developed, but the sign was very marked in hyperpyretic forms of this disease, so that one cannot be guided by this sign in the differential diagnosis of meningitis from typhoid fever. This opinion is quite opposite to that of older observers, like Blümm, and Kernig himself, who pointed out the significance of the sign in the differential diagnosis between typhoid and meningitis.

On the other hand, not all cases of meningitis have Kernig's sign. Packard,[8] in three cases of meningitis—two tuberculous and one pneumococci—could not demonstrate this phenomenon. The same result was reported by F. S. Clark,[9] apparently confirming Henoch's observation that Kernig's sign is not characteristic of the tuberculous form of meningitis.

The presence of Kernig's sign in nervous lesions having little or nothing to do with meningitis had already been shown by Bull, who observed it in a case of cerebellar tumor and in one of thrombosis of the left transverse sinus. Recently, W. Thyne,[10] has described a case of hemorrhage in the left lateral lobe of the cerebellum, in which the sign was positive.

Sailer[11] also reports two neurological cases in which Kernig's sign was positive. The first case was one of hemorrhagic softening of the ascending parietal convolution that extended inward through the centrum ovale toward the internal capsule which was not involved. The second case showed cerebrospinal symptoms, such as defective speech, eye symptoms, pains in the back and in the left arm and leg, spasticity, etc., without any diagnosis having been made by the author (meningitis?) Sabrazès[12] claims that Kernig's sign may be demonstrated in tabes during the crises. When the crises is over the sign disappears.

The majority, however, of observers have pointed out the constancy of Kernig's sign in acute meningitis, its very rare occurrence in other diseases and almost complete absence in normal conditions. Herrick[13] studied nineteen cases of meningitis and found the sign in 89.4 per cent. In twenty-five healthy individuals, Kernig's sign could not be demonstrated. In one hundred cases of diseases other than meningitis, Herrick found the sign *absent* in 99 per cent. Osler,[14] in one of his articles says that Kernig's sign was always present in his cases of cerebrospinal meningitis. Netter found Kernig's sign present in twenty-one cases out of twenty-three. W. Shields[15] examined one hundred *non-meningitic* cases, and only in five was the sign positive. These cases were as follows: one case of uremia, two of typhoid fever, two of right-sided hemiplegia.

All observations regarding Kernig's sign were carefully conducted and studied by competent observers, and cannot leave any doubt that Kernig's sign is indicative of some lesion of the spinal membranes. The nature of the lesion may be determined by bacteriological and histological examinations (lumbar puncture with the examination of the fluid obtained, lymphocytosis, etc.)

If there is not and cannot be great difference of

opinion concerning the frequency of Kernig's sign in different forms of meningitis, there is great controversy regarding the pathogenesis of this phenomenon, and we may say that there are as many theories as authors, that have endeavored to explain the essence of Kernig's sign. Some of them, like Sailer, declare that the mechanism of Kernig's sign is obscure, being probably due not to a lesion of the meninges, but to an irritative lesion of the pyramidal tract that diminishes, but does not destroy its functional activity.

More probable, though not always clear, explanations of the pathology of Kernig's sign have been offered by Bull, Chauffard, Cippolina and Maragliano, Roglet, and Piéry. Bull thinks that Kernig's sign represents only exaggeration of normal phenomena. In a healthy individual with the thigh flexed at right angle, the leg being stretched, no reflex action will result, as the stretching is too insignificant to prevent full extension of the knee. However, the stretching of the leg is sufficient to produce cramp-like reflex contraction of the corresponding muscles, if there be present some cerebral lesion or increased pressure in the brain.

Chauffard[16] explains Kernig's sign in the following way: normally there exists in both the upper and the lower limbs a very slight degree of flexion (semiflexion) which, however, is readily reducible. The semiflexion is brought on by the equilibrium existing between the antagonistic muscles. In meningitis we have to deal with muscular hypertony; at the slightest change of the attitude, contraction sets in in the antagonistic muscles with physiologically predominated action. The slight physiological predominance (for the lower limbs it is in the flexors) is almost balanced when the muscular tonus is normal, and, if increased, it brings Kernig's sign. The latter is, therefore, determined by Chauffard as "uni-multiregional contraction of physiologically predominant muscular groups, which contractions occur in attitudes normally bringing this predominance into play." A similar explanation is given by Cippolina and Maragliano.[17] According to these authors Kernig's sign is merely an exaggerated physiological phenomenon, because normally, if the thigh be forcibly flexed upon the body, a slight flexion of the leg always takes place. In meningitis this flexion is much more marked. The phenomenon is due to the loss of equilibrium between the flexor and extensor muscles of the thigh. The flexors are in a state of hypertony, the extensors in a state of "active insufficiency," *i.e.* their contractive power is decreased, while that of the flexors is increased. The decrease and increase of the contractive power of muscles have very much to do with the points of muscular insertions being approached to or removed from each other, while the patient is sitting or lying.

A good explanation of Kernig's sign is given by Roglet,[18] who ascribes the hypertony of the flexors in meningitis to the irritation of spinal roots. The muscular hypertony leads to loss of elasticity and, perhaps, to diminution of the length of the muscles. The latter become too short to permit of complete extension of the leg when the femur is flexed upon the trunk. Finally, Piéry[19] sees in Kernig's sign only a defensive contraction of the flexor muscles of the thigh reacting against the painful elongation of the inflamed nerves of the cauda equina. The elongation of the nerves occurs when the thigh is forcibly flexed upon the pelvis, the leg being simultaneously extended (Kernig's position).

On the ground of anatomic physiological data, we can give the following explanation of the pathogenesis of Kernig's sign. When the thigh is flexed upon the trunk, and the leg at the same time is extended (Kernig's position), the sciatic nerve becomes stretched.

Thus in Kernig's sign we have, first of all, to do with the stretching of this nerve. In the healthy state, the stretching of the sciatic nerve seems not to produce any pathological conditions, since Kernig's sign has never been clearly demonstrated in healthy individuals, except when the thigh is flexed upon the trunk at a very sharp angle, *i.e.* when the sciatic nerve is greatly stretched. In morbid conditions, when the nerve itself is affected (neuritis-sciatica), or the nerve roots are affected—which undoubtedly takes place in acute meningitis[20]—the stretched, affected roots react correspondingly; the posterior roots, by producing pain, which in Kernig's sign is pointed out by the majority of observers, and the motor roots, by producing contraction of the corresponding muscles, in the case of the sciatic nerve, the flexor muscles.

The pain arising from the stretching of the posterior roots makes the patient instinctively keep away from further stretching of the posterior roots, as it happens, for instance, in dislocations when the muscles respond with strong contraction to any active or passive movements in the dislocated joints, so that this explanation, which may be considered as a combination of Piéry's and Roglet's explanations, may be held, at least, as the simplest one we have for the understanding of the mechanism of Kernig's sign.

The occasional occurrence of Kernig's sign in typhoid fever may be explained by the fact that the meninges are frequently affected in typhoid fever ("meningo-typhoid" of Curschmann), so that the sign is due, not to the fever, but to the concomitant meningitis.

Regarding other published cases we had mentioned above in which Kernig's sign was present in the apparent absence of meningitis, it is hard to prove that in those cases the meninges were not affected, so that, commonly, Kernig's sign may be considered as a standard sign of inflammatory meningeal lesions, and, as being due to irritation of the spinal roots, produced by the stretching of the sciatic nerve.

# THE MECHANICS OF DORSAL POTT'S DISEASE.*

By JOHN C. SCHAPPS, M.D.,

BUTTE, MONTANA.

LATE ORTHOPEDIC SURGEON TO THE ST. MARY'S GENERAL HOSPITAL AND THE KING'S COUNTY HOSPITAL, NEW YORK CITY; MEMBER OF THE AMERICAN ORTHOPEDIC ASSOCIATION; ORTHOPEDIC SURGEON TO THE ST. JAMES HOSPITAL, ORTHOPEDIC SURGEON TO THE PAUL CLARK HOME, BUTTE, MONTANA.

Although the victories of orthopedic surgery over deformity have been many and brilliant, we have still to face at every turn the worst of deformities—the dwarfed, distorted, pathetic figure of dorsal Pott's disease. These cases must frequently be treated at home—by the family physician and by means of home-made contrivances. It is the object of this paper to present the fundamental mechanical principles upon which such contrivances should be constructed and used, and more especially to point out mechanical errors which should be avoided.

An examination into the anatomy of the part, the mechanics of the deformity and the actual working mechanism of the conventional apparatus will explain why this deformity has not been controlled as has that of spondylitis of the cervical or lumbar region. The cervical and lumbar portions of the spine are isolated columns connected with the adjacent parts of the skeleton only by muscles. They are flexible. They bear their burdens upon their convexities. The dorsal portion has very different conditions and relations. Each rib is firmly attached to a vertebra at two points, one behind the other and is practically a continuation of the vertebra. The ribs are vertically stiff. They fuse into the sternum and thus form a vertical arch or truss which would appear to be ample support upon the anterior or concave side of the spine under any degree of weakness. With its shape and position, had this anatomical arch sufficient rigidity, it would indeed serve as a substantial brace. Destruction and deformity in Pott's disease are the results of motion in and pressure on diseased bone. It is remarkable that, although the dorsal vertebræ are thus braced and are firmly—in the mid and upper region almost immovably—secured to each other and to the thorax, disease in this locality is characterized by more obstinate tendency to destruction and by greater and further reaching deformity than that of the cervical region where motion is greater or that of the lumbar portion, where both motion and pressure are greater.

The destruction is primarily due to the mechanically central position of the part as compared with those above and below. Besides its burden of pressure from weight and muscular action, which is borne upon the concave and weaker side, it is subject to the strain of movements of the head, of all four extremities and to the up and down motions of the ribs which are direct and incessant traumatisms. The instinctive effort to avoid them produces a guarded, grunting respiration. The spinal displacement is largely caused by force applied through the long bones connected with the spine. And, conversely, the connected bones are displaced by its deformity. When left to themselves, they furnish more leverage to deform than support to protect. As the spine softens and bends under downward pressure exerted directly upon it and upon the ribs, the ribs are tilted. In the diagrams (Figs. 1 and 2) AB represent the first pair, CD the seventh and longest pair of ribs, BD the sternum, and AC the upper dorsal spine. Let softening occur at X. The upper ribs being short and the lower being long and inclined downward, the lower end of the sternum is swung forward upon the upper, and the front of the chest, the crown of the arch is displaced forward and buckled. The spinal deformity cannot possibly take place except by this sternal protrusion. In dorsal Pott's disease, the weakest point, the point where support may be most advantageously applied, is the lower front of the chest.

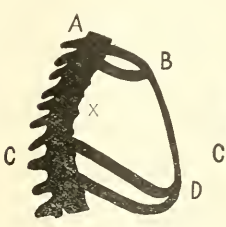

Fig. 1. The normal relations of the first and seventh pairs of ribs, the intervening dorsal vertebræ, and the sternum; diagrammatic.

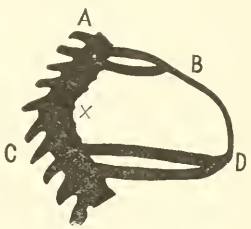

Fig. 2. The buckling of the interior arch and the upward tilting of the lower ribs in dorsal Pott's disease; diagrammatic.

As the spine bends more and more, the bending strain is exerted more and more anteriorly and at greater mechanical advantage. Posteriorly the spinous processes separate as far as the ligaments will permit, flexion being slight here, when the ligaments act as does the hinge of a nutcracker or lemon squeezer, the diseased bone representing the nut or lemon. Under leverage exerted upon the forwardly inclined upper spine and upon the ribs extending forward from it, the softened bone is rapidly deformed and destroyed. The thorax if not supported now protrudes in front and behind and is contracted vertically and laterally. The patient's height is further diminished by increase in cervical and lumbar curvatures necessary for the maintenance of equilibrium. The protrusion of the lower front of the chest is facilitated by the sinking of the chest toward the pelvis and the consequent relaxation of the abdominal muscles and fasciæ.

Motion and downward pressure being the destructive and deforming forces, the indications are to reduce them to a minimum. This is accomplished most completely by fixation in recumbency upon a well fitted surface. Because of its central position, the dorsal spine cannot otherwise be adequately put at rest. Motion is thus reduced almost to that of the quiet breathing of general rest. The cessation of the grunting affords the best possible proof of the propriety of the measure. Pressure is reduced to that of passive muscular tension and may be further diminished by traction. The force of gravity, which, in the upright position deforms and destroys, may now be utilized to protect the spine from de-

* Read at an annual meeting of the Montana State Medical Association, Butte, Montana, May 18, 1905.

struction and deformity. The Bradford frame, to which Whitman and Selva (Trans. Am. Orthopedic Assn., XIV) have made valuable modifications has been of immense service in dorsal Pott's disease. The best and quickest results are obtained by treating the spine with the same gentleness as if it were fractured or otherwise acutely affected. Motion and pressure, though painless, are not harmless. A great deal of damage is done in bone tuberculosis simply because the part has not the sensitiveness which accompanies more acute conditions. As tersely expressed by Ridlon and Jones (Lectures on Orthopedic Surgery, 1899): "In the upper dorsal region from the first to the sixth vertebra, the deformity may be expected to increase under any form of treatment which does not include prolonged and uninterrupted recumbency as its essential feature." This is equally true as to the efficacy of recumbency and the inadequacy of the old methods of treatment in the upright position.

The upright position should be deferred until the acute stage has passed and the change should be a gradual and careful experiment. Portative apparatus is always employed. It is universally admitted that the forms in general use and described in the standard text-books upon orthopedics do not, even in the most skilled hands, control the deformity. They are applied with the intention of fixing the spine, applying leverage, and relieving it from vertical pressure as one would splint a broken long bone. To do so requires a grasp upon the spine above and below the diseased part and somewhere near to it. In dorsal disease there is no upper hold nearer than the head, and below none nearer than the pelvis. The diseased area is separated from each by a chain of joints. It is a common fallacy to think that by securing a brace to the back and including the whole trunk within the grasp of the instrument the portion of the spine covered is thus fixed. Another fallacy is that of the efficiency of spinal leverage in dorsal disease. Under downward pressure from weight and muscular action, instrumental traction backward upon the head and pelvis against forward pressure upon the dorsal spine must first increase the flexible cervical and lumbar curves. And not until their limits have been reached can any inhibition be exerted upon a dorsal kyphos. Pressure cannot be applied to the front of the neck to prevent the cervical lordosis. Pressure on the upper front of the chest is of service according as the diseased part is low in the dorsal region and as it is pressed forward. The abdomen is an air cushion and is too soft to transmit pressure for the prevention of the lumbar lordosis or to afford counter pressure to hold the diseased dorsal spine forward. Abdominal pressure, besides being mechanically useless is, by interfering with the respiration of a tuberculous patient, distinctly injurious. It also tends to produce uterine and other visceral displacements and hernia. And when the abdomen is distended by food or gas, the pressure of the instrument is taken off the part where it might be useful.

Another fallacy is as regards vertical relief. In cervical and upper dorsal disease downward strain may, by means of a pelvic band, spinal uprights and headpiece, or by means of plaster jacket and head-piece, be advantageously transferred around the seat of disease. Here the burden is light, the bridge short, it is on the concavity and so subtends the curve, and the whole trunk serves as a pedestal. But in mid or lower dorsal disease the stress of weight and muscular action is great, and the bridge must reach from the head around the curve to the pelvis. If spinal uprights are used they must, to have sufficient rigidity, be heavy. Whatever the material, the burden must be borne entirely upon the projections of the pelvis. It is doubtful whether the soft parts there actually tolerate more pressure than the weight of the apparatus. The undeveloped pelvis of a child certainly cannot. When the spine is much bent, the appliance may and frequently does take a downward bearing above the diseased part and contribute to the weight carried by it. In dorsal disease, a rigid support extending from the lowest point of the pelvis upward into a head-piece has simply the great merit of limiting motion.

But, while apparatuses designed to fix or draw upon the dorsal spine have necessarily failed for want of grasp, mechanical possibilities are not exhausted. The anatomical arch should be supported and retained in the best possible relation to the dorsal spine. For this purpose, pressure backward must be applied to the front of the chest, especially to the lower end of the sternum and the cartilages extending downward and outward from it, against forward pressure upon the diseased vertebræ. The support is that of a tie rod passing horizontally through the chest. It should be the fundamental principle of treatment in dorsal Pott's disease in the upright position. For a small amount of pressure thus exerted has great sustaining power, especially when the protrusion has not advanced. And it is mechanically impossible for the spine to buckle very much if the integrity of the arch be preserved. The lower ribs must be permitted to spring out laterally. Pressure upon the sides of the chest and upward pressure under the lower ribs promotes anterior and posterior protrusion, and must be avoided.

That none of the conventional apparatus is designed upon a recognition of the mechanical importance or even the existence of the anatomical arch is evident from the fact that they either do not support it at all, or do so accidentally, making at the same time pressure elsewhere, which neutralizes the support and promotes the deformity. The solid plaster jacket has the merit of anteroposterior rigidity, but presses upon the sides of the chest and under the free borders of the ribs. It is uncleanly and has other well-known disadvantages, one being that as the parts pressed upon are out of reach, one does not venture to apply as much pressure as might be used if they were accessible for the examination and care of the skin. For fear of having to remove the jacket because of a sore back, the kyphos is padded or a window is cut so that pressure is diminished there while that at the sides remains. Soon the trunk sinks into the jacket, wedged in from side to side, the lateral pressure increasing as it descends. When the jacket is cut down the front and laced, its pressure is almost purely lateral. The Taylor bivalve jacket has much in its favor, but it covers parts where pressure is not required. As a material for spinal support, plaster is heavier and more clumsy than steel bars, and cannot be modified. Jackets of other materials than plaster have each some of its disadvantages. The posterior metal supports secured by soft apron lacing or straps around the chest and abdomen contain no provision against the buckling of the arch. Many are so much narrower than the trunk that their action is almost purely compressive. Their force is largely expended upon the abdomen and the yielding sides of the chest, and by constricting the waist they push the ribs upward.

About eighteen years ago, observing a case of mid-dorsal disease from which the jacket was removed and replaced by one of these instruments, I was greatly impressed by the rapid increase of the deformity, and with the entire absence from the appliance of any obstacle to its advance. It then seemed

to me that what was needed for such cases was an apparatus which, while affording the same rigid anteroposterior support as the jacket would press only where pressure was necessary, and not where it was useless or injurious, which might be readily removed for the inspection of the deformity and for the toilet, which might be adjusted and modified, and by which pressure might be more freely applied than when its effects cannot be watched. I felt then that the pigeon breast was not merely incidental, but that it played an essential part in the production of the spinal deformity and must be reckoned with in its prevention.

The result was an anterior rigid support first applied in 1892, presented at the Orthopedic Section of the New York Academy of Medicine in 1895, and described in the *New York Medical Journal* of that year. The apparatus has been modified in several details, and adapted to the treatment of cervical and lumbar Pott's disease, but for the treatment of dorsal disease, the fundamental principle of arch support has been preserved. I use it in combination with the Taylor back brace, with long cross pieces and U-shaped hip band, though it may be used with any sort of posterior brace, and tie rod pressure may be supplemented by as much fixation, leverage, and vertical support as are possible. Both front and back braces are so simple that any machinist or blacksmith can make them from patterns furnished by the surgeon. They should be fitted to the patient, and refitted whenever necessary. (Figs. 3 and 4.)

Commencing at the lower end, the front brace presents a flat steel band, which crosses the abdomen as low as possible without being displaced by the thighs when the patient sits, and extends closely

Fig. 3. The author's front brace.

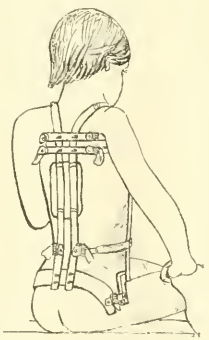

Fig. 4. Modified Taylor back brace.

around the sides of the pelvis and downward for two or three inches to a level with the horns of the posterior hip band, with which it is connected by straps. The pelvis is clamped between the bands, which nearly meet at the sides. The anterior superior spines are protected by pads of kersey and leather, and the middle portion of the front band is arched forward so that, when the patient is supine, there is a space behind it of an inch and a half or more. This will be filled by the abdomen when the patient stands. (Fig. 5.) At the location of the anterior superior spines flat uprights are riveted at right angles, or, if the abdomen is very protuberant, the uprights are directed slightly outward. They reach nearly to the top of the chest, and at the level of the axillæ are crossed by a flat band extending around the sides of the chest and nearly meeting the cross piece of the posterior brace. Holes half an inch apart in the uprights will facilitate the placing of this chest band. Or the uprights, pelvic, and chest bands may be made in two pieces overlapping

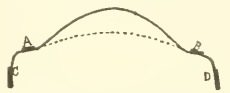

Fig. 5. Plan of pelvic band of front brace; A, B, uprights; C, D short flat pieces extending downward and carrying straps to connect with the posterior pelvic band; the dotted line indicates the line of the abdomen when the patient is supine.

and fastened by screws, so as to be readily shortened or lengthened. In measuring a supine patient, the thigh should be flexed to a right angle and the shoulder drawn well down, or the chest band will

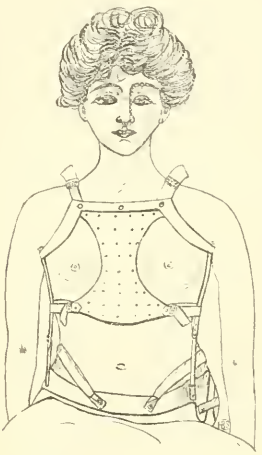

Fig. 6. The author's front brace for a woman; the iliac straps are shown as arranged for vertical support.

be too high when the patient stands. No. 16 spring steel is a good material, the pelvic band one inch wide, the others one-half inch. These dimensions are for children. The perforated stiff leather shield shown in the cuts is attached by the rivets, which secure the chest band to the uprights, and is supported at the top and bottom by adjustable straps between them. Near the lower ends of the uprights are padded web straps passing over the iliac crests to buckles upon the uprights of the back brace. When vertical support is desired, these straps are attached to the front and back pelvic bands. The ends of the chest bands may be padded as crutches, or padded shoulder straps from the top of the back brace may pass through the axillæ to a second cross-piece behind. When the chest is flat and the dorsal spine nearly upright, the backward pressure of the upper part of the shield exerts spinal leverage. When the deformity has advanced so that the upper part of the sternum inclines forward, backward pressure there is not possible, and the apparatus need not be extended above the axillæ. The pressure of the lower part of the shield, supporting the arch, is available in any stage of deformity, and will be found to give much relief in advanced cases.

For women, the uprights pass directly up the sides to the axillæ, and are connected at the top by a piece of sheet steel, shaped as shown in Fig. 6. They establish a vertical transverse plane toward which the protruding parts of both front and back may be drawn. This arrangement and the downward extension of the lower front band are the suggestions of Dr. Clayland of Brooklyn.

This combination of front and back braces constitutes a skeleton support, to which parts may be added to meet the requirements of a peculiar case or the preferences of the surgeon. In cervical or high dorsal disease, where a head-piece is used, the trunk is grasped by all available contact without abdominal pressure or interference with the lateral movements of the ribs. The anterior uprights furnish poins of counter pressure to any part of the dorsal or lumbar spine. In dorso-lumbar, or lumbar disease, the descent of the chest is opposed by straps under each side from front to back upright.

By placing cases of dorsal disease early in recumbency, and following it by arch support, dorsal disease may prove as controllable as cervical or lumbar—perhaps more so.

Owsley Block.

## THE EAR COMPLICATIONS OF CEREBROSPINAL MENINGITIS.*

By CHRISTOPHER J. COLLES, M.D.,

NEW YORK.

Earlier writers on the subject of cerebrospinal meningitis, and whose observations were made mostly during epidemics in different countries, have not said much that is definite or, indeed, trustworthy concerning any ear complications coming to their notice. We find this subject usually dismissed with the remark that the patient became very deaf, or slightly deaf, or that when convalescence set in there was absolute deafness present, etc.

Thus Ames, in an account of an epidemic of cerebrospinal meningitis which prevailed in Montgomery, Ala., in the winter and spring of 1848, says that "spontaneous deafness" was noted in a few patients, "in one of whom there were three exacerbations of it on the second day, each lasting about three hours, with intermissions lasting about the same time." This somewhat vague statement is cited to show the superficial and altogether useless consideration such aural symptoms appear to have aroused. Levy, in his elaborate brochure on the same subject in 1849, makes also no mention of aural complications, and Clymer (in 1872) dismisses the matter with the unsatisfactory remark that "the disorders of the organ of hearing, though happening, are by no means constant; some degree of deafness and buzzing in the ears are the most common." Recent observers have been more explicit, and such authorities as J. Lewis Smith, Knapp, Bell, Stillé, Upham, and Moos have called especial attention to the loss of hearing occurring among cases of this disease.

It may be of interest here to note the following observations from a statistical standpoint: Knapp examined thirty-one cases, and in all of them the deafness was complete, and, with two exceptions, bilateral. Among the twenty-nine cases of total deafness but one recovered any hearing power whatever. Moos states that of sixty-four cases which showed disturbance of hearing as a sequel to cerebrospinal meningitis, twenty-nine were totally deaf on both sides, two totally deaf on one and hard of hearing on the other side, and one case had only impaired hearing in both ears. Smith reported that from his observations in the epidemic of 1872, about one in every ten patients became deaf. Deafness was noted by Upham in 1874, as occurring in twenty-one out of three hundred and fifteen cases of cerebrospinal meningitis. Sexton recorded twenty-six cases of aural disease arising from an attack of cerebrospinal fever. Of this number, seventeen were deaf mutes, while five were either totally deaf or nearly so. Hobby observes that cerebrospinal meningitis is apparently equally important as a cause of total deafness with scarlet fever, and really much more so, because many illnesses called "fever," "congenital," "unknown," are really cases of cerebrospinal meningitis. Both European and American statistics show that one-fifth to one-sixth of all cases of acquired deafness are due to cerebrospinal fever alone, whilst at various times and places the proportion caused by this disease has been much greater.

That many deaf-mutes owe the origin of their condition to an attack of cerebrospinal meningitis in their infancy is a well-recognized fact. Graham Bell, in his "Memoir upon the Formation of a Deaf Variety of the Human Race," shows by the statistical reports of two deaf and dumb asylums that there was a very remarkable increase in the number of deaf-mutes in these institutions following epidemics of cerebrospinal meningitis; and Ziemssen states that in the deaf-mute institutions at Bamberg and Nüremberg, out of ninety-one pupils eighty owed their infirmity to this disease. Indeed, Dr. Roth, in 1874, found that all the pupils in the deaf and dumb institution at Bamberg, forty-two in number, were deaf from this cause. These few observations, taken from the statistics on the subject, will demonstrate how important a rôle cerebrospinal fever plays in the production of deafness.

When we come to a consideration of the aural affection itself and the seat of the lesion, we shall find that opinions vary. It would appear, according to the views of some authorities, that in certain cases an inflammatory lesion at the acoustic center in the brain, or occurring along the course of the nerves of hearing to the auditory foramina through pressure of plastic exudation, might be responsible for the loss of hearing. As evidence, however, that the origin of this affection is not central, Gruening obtained by electrization the normal reaction of the auditory nerves within the cranium. If the lesion which causes the deafness lies along the course of the auditory nerve within the cranium, the function of the other cranial nerve should be destroyed also. If the inflammation did not involve the labyrinth, but simply damaged the main branches of the auditory nerves, it would be difficult to understand how the trunks of the facials could escape, so intimately related as they are to the former nerves. It is much more probable (and indeed is now generally accepted) that an inflammatory condition of the labyrinth is the causive factor, especially in those cases of profound and lasting deafness. This opinion is borne out by actual post-mortem findings. Heller, Lucae, and Klebs have reported undoubted evidences of labyrinthine inflammation in autopsies. Fibrinous adhesions existed between the bones of the internal ear and the walls of the vestibule. Klebs states that the mucous lining of the vestibule was detached, the lining membrane of the semicircular canals was distinctly thickened and loosed, and in the anterior canal there were semifluid purulent masses. We have been shown by Weber-Liel (in 1879) that a free communication exists between the endolymphatic and perilymphatic spaces of the labyrinth and the extralabyrinthine intracranial spaces. It is very probable that infection spreads by this route from the meninges to the labyrinth. The inflammatory process extends along the lymph channels of the vestibule and cochlear aqueducts, involving the structures within the bony labyrinth.

*Read before the Gouverneur Alumni Society, February 1, 1905.

The composition of the perilymph and endolymph undergoes a change, due to the presence of the specific germ, the blood vessels become dilated, and true tissue-hypertrophy takes place from the migration of white blood cells into the surrounding tissues. Owing to these changes in the blood supply, extravasation of blood takes place easily and is often found. The tissues become dense, bone-thickening takes place, and often the semicircular canals or cochlea are partially, if not completely, obliterated. In other cases the tissues become necrotic, and we find the labyrinthine structure filled with purulent matter. In some rare instances it has been found that the tympanic cavity has become involved by the purulent process of the internal ear breaking through the oval or round windows. In this manner a purulent otitis media may be established. As far as we know, this form of labyrinthine disease does not differ from that occurring during the course of other epidemic affections, such as scarlet or typhoid fevers, measles, etc.

Another aural affection frequently observed in cases of cerebrospinal fever is acute inflammation of the middle ear. Indeed, a mild otitis media is of common occurrence, but usually subsides without any impairment of the hearing power. In some cases a more severe attack of otitis media becomes a suppuration of the middle ear. Moos reported a case of cerebrospinal meningitis in which decided, if not total, deafness was found two days before death. At the autopsy it was seen that the tympanic mucous membrane on both sides was decidedly hyperemic and swollen. The auditory nerve in the porus acusticus internus was quite free from evidences of inflammation on both sides, and both labyrinths were normal in every respect. Klebs also has reported a similar case, where the deafness began shortly after the commencement of the illness, becoming complete in a few days. At the postmortem examination the auditory nerves (examined microscopically) were found perfectly normal, and the terminal apparatus of the cochlea also. Extensive inflammatory changes, however, were found in the middle ear, the cavity being filled with bands of connective tissue traversing it in all directions, greatly impeding the free movement of the ossicles to which they were firmly adherent.

But this affection, while severe in some instances, cannot satisfactorily account for the profound and complete deafness in by far the greater number of cases, nor for the important fact that deafness is almost invariably bilateral. It may not be total when first observed, only partial; but it will usually be found to increase gradually, becoming complete after some days or weeks.

Most of the unfortunates whose hearing is affected become perfectly deaf, and never regain this function. Otalgia, otorrhea, and other local symptoms are, for the most part, entirely absent, excepting, perhaps, vertigo and tinnitus, to which reference will be made further on. The loss of hearing does not occur at the same period of the disease in all cases. Some patients emerge from the stupor of the disease with good hearing, but lose it during convalescence; but the majority are observed to be deaf as soon as full consciousness returns.

It is difficult to understand how any attack of acute otitis media could cause such profound and complete deafness, and practically all otologists today are united in the opinion that the labyrinth is the seat of the trouble. As has been just stated, aside from the deafness we sometimes observe vertigo and intense tinnitus. The noises, coming on suddenly, may be agonizing in their intensity. A real hyperacusis may precede these attacks, sometimes so marked as to be painful, making the patient start at the slightest noise. This is easily explainable from the condition of hyperemia in the labyrinth. The subjective noises gradually become less severe, owing to destruction of the terminal filaments of the eighth nerve, and the vertigo disappears.

Physical examination is absolutely negative, the parts presenting a normal appearance. If any power of hearing remains, it is usually for low notes. Bone conduction is diminished, and soon altogether lost.

The outlook for recovery of the hearing power is a grave one. In some milder cases a certain amount of hearing may remain. In early life, even after the child has learned to speak a few words, the loss of auditory perception renders the patient mute as well as deaf, such words as the child has learned being soon forgotten. Treatment is unsatisfactory, though it is claimed by some that favorable results have been obtained through reduction of the labyrinthine pressure by the use of pilocarpine. The general prognosis is a gloomy one, and any improvement in the hearing, however slight, should be considered most encouraging.

In concluding these few remarks it might be of interest to state that the writer was given the opportunity last July of examining eleven cases of cerebrospinal meningitis at the Gouverneur Hospital, as to the condition of their ears. Five of these patients were boys and seven girls. They were all little children in various stages of the disease. In but two of them were there any evidences of ear disease present, subjective or objective. In the one, a girl, both drum-membranes were congested, and the child complained much of earache. The other case, a boy, showed a congested right drumhead; but the child gave no sign of any subjective symptoms. This last-mentioned child had, in addition, a profuse nasopharyngeal discharge, his pharynx being congested and filled with thick viscid mucus.

## ECTOPIC GESTATION COMPLICATED BY MENTAL DISTURBANCE.

By FRED. G. HODGSON, M.D.,

ATLANTA, GA.

Mrs. N., age twenty-three, married, stenographer, came to me May 1, 1905. Her mother, who is dead, had been of very nervous temperament. Her father is alive and well. The patient was married once before, but divorced. She has had attacks of pain in the right ovarian region and a leucorrhea. She has always been very nervous, and has hysterical attacks. Menstruation has been regular and normal. The last menstrual period began about two weeks ago, and she has continued to flow ever since. She had skipped no period. She has considerable pain in the right ovarian region. Urination is painful and frequent. The patient is constipated; she can give no reason for her present condition. Has never been pregnant.

A simple mixture of viburnum, hydrastis, etc., was given. The patient reported in two days that the pain was better, but the flow continued. She was told to remain in bed and continue treatment. I saw her the next day, and, after pointed questioning, she confessed to a secret marriage; also that she and her husband had both been suffering from morning nausea. Her breasts were enlarged and slightly tender. I suspected a miscarriage, and advised curettage. They preferred to wait. The next week she had a severe attack of pain in the right side of the pelvis and in the rectum, which required morphin to relieve. There was no elevation of the tem-

perature, and pulse remained about 80. Pelvic examination was difficult and unsatisfactory, and no mass could be felt. Examination of the vaginal secretion revealed many gonococci. The bloody discharge was less. She had numerous attacks of pain, and some were relieved by sterile water hypodermics. The next week signs of pelvic peritonitis began to develop, so she was taken to the Presbyterian Hospital. After reaching the hospital, the pain became worse, and her bowels could not be moved for thirty-six hours. We finally succeeded with high enemas. Now, for the first time, she began to have hallucinations—seeing persons in the room, and delusions particularly in regard to her husband. She talked confusedly and incoherently. I decided to operate at once, and did so on June 1.

The patient was anesthetized (chloroform and ether) and placed in the lithotomy position. Pelvic examination revealed a large mass in the cul-de-sac; an aspirating needle was inserted and blood withdrawn. The diagnosis of ectopic pregnancy was definitely made. Patient was curetted, then changed to Trendelenburg position. The abdomen was opened in the median line just above the pubes. A large blood clot was found in the pelvis and removed. The right tube was very much enlarged, and showed a rupture about its middle. The tube and ovary were dug out of a mass of adhesions and removed. The wound was closed in layers with catgut. The rectum was dilated for the relief of hemorrhoids.

Patient rallied well, but her mental condition was a little worse. She was restless, talkative, removed the dressings and accused others of doing it. She had a slight rise in temperature for a few days, never above 101°, but this subsided by the sixth day, and remained normal. On the third day she got up out of bed before she could be stopped. Was very noisy and violent. The wound healed by primary union.

About the tenth day she got out of bed and tried to jump out of the window. Remaining in the hospital seemed to aggravate her mental condition, so on the fourteenth day she was taken home in an ambulance. After two days, her mind began to clear up, and by the twenty-first day she was perfectly rational. She remembered some of her hallucinations and delusions. Since then she has continued to improve in every way, and has had no mental disturbance. She was discharged cured June 22, 1905.

## EYE INJURIES DUE TO BLOWS FROM THE CORKS OF GINGER ALE BOTTLES.

BY CHARLES GRAEF, M. D.,

NEW YORK.

My experience with two cases of injury of the eye due to a blow from the cork of a ginger ale bottle, leads me to draw attention to the very real danger connected with this sort of vessel—a danger that should not, and need not, be permitted to continue. The cases were similar in that both occurred in women, each of whom was struck in the left eye by the cork which she had released from such a bottle by pressing back the wire spring holding the stopper in place.

The force of the blow in the first case was sufficient to paralyze the iris and to give the patient a "black eye" of picturesque extent and the usual duration. While there were no other intraocular effects noticeable, her vision did not return to normal for some days.

The second patient suffered more severely. The blow caused a profuse hemorrhage into the anterior chamber, and it was an anxious few days before the patient was able to see, and I was able to make out that the damage was limited to this part of the eye. She made a good recovery, but I was recently told of another such instance resulting in permanent retinal changes and consequent blindness in the injured eye.

Some years ago, while I was in the out-door service at Moorfields Hospital, London, I had a case of this kind in a barmaid who had received the injury while opening such a bottle in the course of her work. This patient presented a beautiful example of commotio retinæ as a consequence. The lower and inner quadrant of the retina was clouded in several well defined, silvery streaks, which gradually cleared up, and had entirely disappeared two weeks after the accident.

The cases I have seen have fortunately ended satisfactorily, but in view of the fact that this is not always the case, and that these dangerous bottles are very commonly opened by women and children at home, in the presence of others, crowding close eager for the drink, or to see the "fizz," it seems reasonable to insist that this source of danger be done away with. The better class of manufacturers have recognized this fault, and no longer use the old-fashioned wired corks in these bottles.

I do not mean to suggest the need of legislative action on the matter, though many less necessary and worthy are made to serve as an excuse for a new statute, but I urge the profession to say a word in season to call the attention of those about them to the matter. Such a word of warning, accompanied by a suggestion of the accidents that have occurred and their sometimes unfortunate results, coming from a physician will not fail to impress itself on the hearer and, being passed along as these things usually are, will bring about the end desired—the discontinuance of the use of dangerous stoppers in bottles that must necessarily very often reach the hands of persons not qualified to handle them safely.

1076 BOSTON ROAD.

### Some Extra-Routine Views of Tuberculosis Pulmonalis.

R. M. Phelps says that by "early" diagnosis in cases of tuberculosis he means as soon as the diagnosis is made, or in some cases as soon as it is strongly suspected, often before the bacilli are found. For this "early" class he assumes a curability of from 50 per cent. to 75 per cent. in a good climate and with at least moderately good medical advice and friendly care. He believes that curability rapidly diminishes from that early time, and that an unduly hopeful view presented to the patient tends to prevent him from securing the greatest benefit. He believes that every person having tuberculosis should be told as soon as possible. Patients usually refuse to take radical steps early. He declares that prevalent fear of personal transmission does not always work for good. Patients are apt to conceal their trouble as long as possible. It is well known that these patients do not wish to mingle with others having the same disease. As to the question of personal transmission, the writer believes that while it cannot be proved that there is no danger of personal transmission in accompanying a patient, still it is very slight. Finally, he discusses the value of climate. He says that his ideal of treatment is "a best sanatorium in a best climate." He believes that the best climate for these patients is found in the desert area from El Paso to the mountain divide in California, and north to Colorado. He declares that the patient must be educated to the use of any air, damp or cool, for breathing, so long as the body surface is kept well protected. There is no danger in breathing night air. He points out the superior advantage of sleeping under the sky to that of sleeping on the porch.—*The St. Paul Medical Journal.*

## ANOTHER ESSAY AT CREATION.

WHAT is life and whence comes it, has always been the one great question overshadowing in its immensity all the countless enigmas of the universe. Is it a property which matter assumes spontaneously when it has arrived at a certain state or constitution, or is it a principle clinging to a portion only of existent matter and transmitted solely to matter derived from this? Is it a fixed quantity, indestructible and uncreatable, or is it a new creation with each new cell or vitalized molecule, vanishing again into nothingness with the disruption of the bit of organized matter it once informed? Matter—inert matter—so far as regards its constitution, is understood in a measure; we know some of its laws and many of its properties, though, in the light of the discoveries of the past decade, he would be rash indeed who would affirm, with the author of "The Bankruptcy of Science," that the great facts of the universe are now known and all that remains for the chemist or the physicist is to fill in the lacunæ and work out the minor details. The refutation of this conceit came almost as it was uttered in the revolutionary discovery of the radioactive property of matter. Here at once was opened up to the mind of man an immense field, unknown and unexplored, wherein doubtless lies hidden the solution of many riddles, perhaps even that of the beginning of life itself. The few incursions that have been made into this field, barely crossing its boundaries, have already resulted in upsetting, or rather enlarging, our conceptions of matter. The atom is no longer the unit of the material universe; it has been shattered into a thousand pieces, and we now know it as a mere shell enclosing hundreds and thousands of infinitely minute corpuscles.

Dazed by the wonders revealed in so brief a time by a study of radioactivity, men are already asking themselves whether the key to the riddle of life is not within our grasp. The experiments of Prof. Burke of Cambridge, who found something which he conceived might be living matter in sterilized bouillon acted upon by radium, have been seized upon by certain enthusiasts as tending toward a solution of this mystery. In a popular article explaining these experiments, contributed by Prof. Burke to the *New York Tribune* of August 13, he says that the question as to whether the microscopic forms which he has obtained are or are not living things "depends altogether upon what our conception of life is, and upon how broad or how narrow is the definition we are willing to accept of the phenomena of vital processes." The bodies which he saw presented a "distinct indication of growth and segregation. They reach a certain size and then divide." This, he claims, indicates clearly that they are not crystals, and he thinks they are possibly a primitive form of life. But they dissolve in water, and this, though Burke does not admit the conclusion, would indicate that they are not a primitive or any other form of life. In an effort to reconcile these conflicting properties of bacteria and crystals, the author ventures the assumption that the bodies "are in the critical state of matter between the mineral and the vegetable kingdoms, possessing not all the qualities of either, but many of the properties of both: that unsteady or unstable state from which, for anything I know, or any of us can know, one process—though probably not the only one—by which the evolution of living matter from not living matter as we know these, may have taken or be taking place; that critical state, in a word, in which matter, through some hitherto unknown source of energy, may have sprung into life, or fallen into absolute inertness." In other words, the "radiobe," as he calls it, may be "that state of matter that separates, or perhaps unites, the organic and the inorganic worlds."

This is an ingenious supposition, and however contrary it may be to our present conceptions of the gulf that exists between living and non-living matter, is not to be dismissed with a sneer. We cannot accept it yet, nor can we deny its possibility; we can only affirm its improbability. We know there are forms of life apparently midway between the animal and the vegetable kingdoms, and it is barely conceivable that there may be forms of matter having a potential vitality, yet not living, but it does violence to our notions to admit of such a possibility. One might as well accept at once the belief that all crystals are a form of life, for such acceptance "depends" in the words of Burke, "altogether upon what our conception of life is, and upon how broad or how narrow is the definition we are willing to accept of the phenomena of vital processes." The definition of life which he accepts is: "The continuous adjustment of internal to external relations, of an individual to its environment"—a very unsatisfactory definition, which would apply equally to an earth worm and a planet. We would say rather that life is the principle whereby matter is endowed with the inherent power of growth and reproduction and of initiating chemical action within itself. Now, mere aggregation is not growth nor is simple cleavage reproduction, and, so far as the published account goes, that seems to be all that has happened to Burke's bouillon bodies.

Prof. Burke says that "it is doubtful . . . if spontaneous generation can ever be proved to the satisfaction of any one who has made up his mind not to believe in it," but the same may be said of any phenomenon. It is no answer to those who reject as improbable and unproven the assumption that in this instance the beginning of life or even the initial process of a transformation from non-living to living matter has been witnessed. Spontaneous generation is in Burke's meaning, "the development of living organisms from inorganic matter," and we see no evidence that any such development has occurred in his sterilized bouillon. If this enthusiastic experimenter can show that his bouillon bodies

have the properties of living matter—something more than mere addition, division, and solution—he will not find the present day physicist unready to accept the fact, for in these times no scientist worthy of the name has a mind made up not to believe in anything, however inherently incredible, which is susceptible of proof. What is not susceptible of proof lies in the domain of faith, not of science.

## THE STERILIZATION OF DRINKING WATER FOR TROOPS IN THE FIELD.

The fact is unhappily notorious that in war disease claims more victims than does shot, shell, or cold steel. Again, it is equally a matter of general knowledge that typhoid fever, chiefly caused by impure drinking water, is the most common complaint to which the soldier in the field is subject. The medical history of all modern campaigns is full of the fatalities occasioned by typhoid fever, and provides melancholy reading, more especially because so much of this fruitful cause of sickness is preventable.

It is allowed on all hands that with rigid care of the water supply, with the earnest cooperation of the man in the ranks himself, the occurrence and prevalence of typhoid fever among armies in the field might be so decreased as to become almost a negligible quantity. The medical department of the Japanese army, during the war just ended, has given to the civilized world an instructive object lesson with regard to the organization and management of sanitary affairs during a campaign. According to all accounts from the front in the Far East, disease in the Japanese army has been conspicuous principally by its absence. After all due allowance has been made for the extremely strict censorship, which is so prominent a feature of Japanese army organization, the conclusion cannot but be reached that the occurrence of disease among the troops has been small, for if any devastating epidemics had occurred, it would have been impossible entirely to conceal such facts. It must be granted, then, that the Japanese have partially, if not altogether successfully, solved a problem which has so long baffled the army sanitarians of modern Europe and of America. By what means have they effected this great work, and revolutionized to a great extent the course of war? Simply by the extreme care which their army medical department has paid to the soldier's water supply. So minute, indeed, has been their attention to the necessity of procuring water free from disease-bearing germs, that English or American soldiers would have regarded many of the regulations tending to this end as troublesome and unnecessary. It is in the subjection of the Japanese private to orders, and the strict discipline which prevails throughout the army, that the procedure adopted to safeguard the water supply has been rendered possible of accomplishment. The results, however, of Japanese methods to prevent disease in the field have been so markedly successful, that other armies have been stirred to copy, as far as is possible, their preventive measures.

For example, the British Army Service Corps has been conducting experiments for some time past, with the view of discovering a really reliable means of sterilizing water for troops in the field. A demonstration of the various methods to attain this object was recently given at the British Army Service Corps Barracks, which is referred to at some length in *The Lancet* of August 26. The methods of purification illustrated were divided into three sections: (1) those in which the water is sterilized by heat; (2) those in which purification is effected by filtration, and (3) those in which the addition of chemical agents is relied upon to sterilize the water.

Six apparatuses illustrated the sterilization of water by heat, the principle of five of them being the working by heat exchange. Among these was the Forbes sterilizer, an American product. The other sterilizer exhibited was the Leigh-Canney which is simply a boiler delivering 28 to 36 gallons of water sterilized by heat per hour. One field service filter was shown, that of Slack and Brownlow, an apparatus weighing 124 pounds and capable of delivering 100 to 120 gallons per hour when filtering clear water, which rate is considerably diminished when muddy water is being treated. A service water cart was also shown, fitted with Slack and Brownlow filters, the average yield of which is 100 gallons per hour. The Schumberg process, reference to which has been made in the Medical Record on more than one occasion, was tested. This process relies for sterilizing water upon chemical reagents. It was found that the sterilization of one liter of water can be accomplished in from seven to thirty minutes by the addition of 0.06 of free bromine. The bromine is then neutralized by adding a mixture of sodium sulphite and sodium carbonate. It is stated that after a period of about two minutes the odor of the bromine disappears, but the water has a somewhat stale taste. Iodine used in the same way, it is said, leaves the water odorless and does not alter its appearance, nor is any ill effect produced upon the digestive tract or the general health. The employment of several other chemicals for sterilizing water was tested, among these being permanganate of potassium, which is largely used in India for this purpose, and which, added to water in quantities of from two to four centigrams per liter, is said to destroy all pathogenic bacteria.

The results of the demonstration in London are reported to have given great satisfaction. However, a filter or any other method of purifying water for troops in the field, in order to be of practical use, must be simple as well as effective. The American or British soldier is by no means so obedient to discipline as is the Japanese, and he will not use anything of a kind that gives him any trouble. Much of the sickness among the troops in the Spanish-American and Boer wars was due to carelessness and a refusal to take the trouble to observe simple sanitary rules.

## The Advance of Cholera.

The sudden appearance of cholera in Eastern Prussia and the presence of sixty or more cases of the disease among Russian emigrants in Hamburg awaiting transportation to America, gives cause, not for popular alarm but for increased watchfulness on the part of our sanitary guardians. Epidemiologists have for some time been watching this gradual advance of cholera from the East on one of its periodical incursions into western Europe. The movement began in the latter part of 1899. Eastward the disease advanced from India rapidly, invading China and Japan. From Hong Kong it passed to the Philippines, working havoc in Manila and the Provinces

despite the best efforts of the medical officers of the Army and Marine Hospital Service. Its progress westward through Arabia and Persia into Russia has been more gradual. Cholera appeared in Mecca in 1902, and thence spread throughout the Mussulman world, being heard of in Egypt, Asia Minor, and Persia, finally establishing itself firmly in Teheran. From this point it followed the caravan routes into Anatolia, Transcaucasia, and Transcaspia, thence reaching the banks of the Volga. Here it rested for nearly eighteen months, being restrained by some mysterious influence, the nature of which students of epidemics have never yet discovered, and only now has it resumed its march westward. Why should it have remained so long in Russia and then suddenly crossed the frontier? Raftsmen were coming down the Vistula past Thorn and Kulm, and emigrants were leaving Poland and Western Russia for Hamburg and Bremen, sailing thence for New York, but the disease remained behind. The Russian health officials did as little to throttle the epidemic then as they are doing now, and the communication between the Volga, where the cholera hibernated, and the Vistula down which it is now journeying into Prussia, was just as free in the summer of 1904 as in that of 1905, but the infection refused to spread. Suddenly it takes a start and Europe awakes to the peril of a cholera invasion. Epidemiologists tell us that the conditions which retard or accelerate the progress of this disease are climatic conditions, but this is only a term to cloak ignorance. Pettenkofer's subsoil water theory is just as satisfactory and no more intelligible. That there is some influence which affects the virulence of the comma bacillus, or which determines a greater or lesser power of resistance in the human subject, must be admitted, but whether this influence is atmospheric or telluric or neither, it still remains a mystery.

## News of the Week.

**The Situation in New Orleans** is steadily improving, the number of reported cases averaging about ten a day less than a week ago. Up to Wednesday of this week the total number of cases reported, since the beginning of the epidemic six weeks ago, was 2,111, and the deaths numbered 294. The conditions are now becoming worse in some of the neighboring cities, which have relied upon shotguns instead of oil and culicicides as a defense against the fever, than they are in New Orleans.

**Vaccinating a Shipload at Quarantine.**—A steamship arrived at New Bedford a few days ago from Lisbon, having on board a great number of Portuguese fishermen, among whom was one case of smallpox. The authorities at New Bedford have no facilities for the treatment of so many persons, and, accordingly, sent the vessel here. The ship was held at Quarantine and all of the 558 cabin and steerage passengers were vaccinated.

**Germany Threatened with an Invasion of Cholera.**—Absolute authority has been given to the sanitary authorities in the districts of Kulm, Thorn, Graudenz, Marienwerder, Stuhm, and Schwetz for the purpose of preventing the introduction and spread of cholera. Two Russian raftsmen died of the disease at Kulm, and as they were engaged in the Vistula River traffic, the source of the infection is assumed to be somewhere up the river in Russian territory. All bathing houses along the river have been closed, and the water supplies from the river for adjacent towns have been sharply shut off. The inhabitants are obliged to import water or to use that taken from the wells. Cases have been discovered among upward of sixty emigrants at Hamburg, and in consequence the Hamburg-American Steamship Company sent out the *Moltke* with cabin passengers only, the emigrants who were to have sailed in that vessel being detained for observation. Up to September 5 there had been 77 cases and 24 deaths reported in Germany.

**A Legal Decision Regarding the Curability of Cancer.**—The question of the curability of cancer is likely to be brought before the California courts in a suit brought by a woman physician in Los Angeles against the State Board of Medical Examiners. The law empowers the State Board to disbar any physician who may publish "grossly improbable statements" regarding his healing powers, and on the strength of this the board revoked the license of a woman practitioner who advertised a sure cure for cancer. The woman retorts that her claims can be substantiated and offers to cure any person suffering from malignant disease whom the Board of Examiners may send her. She declares she will bring suit against the board for reinstatement and that she will prove to the court that her claim to cure cancer is founded on facts and hence is not "grossly improbable."

**A Definition and Delimitation of Old Age.**—The *British Medical Journal* announces that the London Vegetarian Association has arranged a meeting on October 13 at which the question what period of life should be termed old age will be discussed by a number of gentlemen between the ages of eighty and ninety, who are still engaged in literary, medical, agricultural, and other work. The chair will be taken by Mr. C. P. Newcombe, who is an octogenarian, and other speakers will be Professor Mayor, Mr. Joseph Wallace and others.

**Dr. George Ernest Morrison,** the Peking correspondent of *The Times* of London, who has been in Portsmouth reporting the doings of the Peace Conference, is a graduate in medicine of Edinburgh University in 1887. He is an Australian by birth and has all his life been a traveler, preferring the life of a correspondent to that of a practitioner of medicine.

**Fire at St. Mary's Hospital.**—The ambulance house of St. Mary's Hospital, Jamaica, L. I., was destroyed by fire one day last week. Two horses perished, two ambulances were burned, and the total loss is placed at $6,000. No one was injured. The hospital building was not damaged.

**The Fifth International Congress of Obstetrics and Gynecology,** which was to have been held in Russia this autumn, has been postponed for a year, by order of the Government.

**Two Million Dollars for a Cancer Cure.**—According to the *Pall Mall Gazette* the Brazilian Chamber of Commerce has devoted the enormous sum of £400,000 as a prize to be given to the scientist who shall discover a really enduring method for the cure of cancer. An international committee is to be formed, consisting of two members of the Medical Academy in Rio Janeiro and of four eminent pathologists chosen from London, Paris, and Rome. These six gentlemen will act as the jury in the case of awarding the prize. It is probable that the London journal meant milreis instead of pounds. Four hundred thousand milreis of Brazil would be about $220,000—a tidy little sum even that for a poor doctor to get.

**Fined for Selling Cocaine.**—A druggist in St. Louis was fined $10 on August 24 for selling cocaine to a negress. This is the first conviction under the anti-cocaine law recently passed by the legislature.

**Medical Society of the Missouri Valley.**—This society held its annual meeting in Council Bluffs, Ia., on Thursday and Friday, August 24 and 25, with an attendance of one hundred. Dr. S. Grover Burnett in his presidential address, entitled "Oslerism Bearded, or a Study of Age in Relation to Work," called attention to the fact that Dr. George M. Beard was entitled to priority in suggesting the uselessness of men above forty years of age. Dr. Burnett claims that those who have done their best thinking before forty, do their best mental externalizing afterwards. Beard has shown us that 70 per cent. of life's work is done by the forty-fifth year, and 80 per cent. is finished by the fiftieth year. Also, that only 25 per cent. more actual work is accomplished from thirty to forty years of age than is done between forty and fifty years of age; thus man's retirement at forty would mean a loss to the world of a sum equal to three-fourths of his work done from thirty to forty years of age, to say nothing of the auxiliary unfinished business accumulated before forty and requiring concentrated experience which comes after forty, to shape it into a thing of value. The last half of man's life is unquestionably the best and most favorable part of it, especially if he devotes the first half to thought. Fadism is the product of immature sentiment which age and experience and careful investigation will always cure. Papers were read by Drs. Leroy Crummer, A. C. Stokes, W. O. Bridges, A. P. Condon, and J. P. Lord of Omaha; Fenton B. Turck and W. F. Waugh of Chicago; Daniel Morton of St. Joseph; J. W. Kime of Fort Dodge, Ia.; Herman E. Pearce and C. E. Hardin of Kansas City; T. M. Bogart of Excelsior Springs, Mo. On Thursday evening the society were entertained by the local profession at Lake Manawa. An amendment to the constitution was read changing the date of the annual meeting to the first Thursday in September. The secretary's report showed a healthy condition of the society, 41 new members having been added during the year. The Buchanan County Medical Society extended an invitation to hold the next semi-annual meeting in St. Joseph in March, 1906, which was accepted. The election of officers for the ensuing year resulted as follows: *President*, Dr. John E. Summers, Jr. of Omaha; *Vice-Presidents*, Drs. C. H. DeWitt of Glenwood, Ia., and C. B. Hardin of Kansas City, Mo.; *Treasurer*, Dr. Donald Macrae of Council Bluffs, reelected; *Secretary*, Dr. Chas. Wood Fassett of St. Joseph, Mo., reelected.

**The Cumberland Valley Medical Association,** having a membership of the physicians of Pennsylvania and Maryland living in the Valley of the Cumberland, met in annual session at Carlisle, Pa., on August 29, under the presidency of Dr. V. M. Reichard of Maryland. There was an attendance of about eighty. The election of officers resulted as follows: *President*, Major James Evelyn Pilcher, Carlisle; *Vice-Presidents*, Drs. H. P. F. Unger, Mercersburg; A. C. Maisch, Hagerstown, and George C. Borst, Newville; *Secretary*, Dr. J. J. Coffman, Scotland; *Assistant Secretaries*, Drs. P. R. Koons, Mechanicsburg; H. C. Devilbiss, Chambersburg; T. C. R. Miller, Mason-Dixon; *Treasurer*, Dr. J. J. Koser, Shippensburg.

**A Breath from the Golden Gate.**—The San Francisco *Chronicle* of August 10 contains the following appreciative comment: "The doctors in New York are concerning themselves about the health of the school children, and are making startling assertions calculated to prepare the public mind for a grafting proposition. The outcome of the thing will probably be the appointment of a raft of political doctors whose chief duty it will be to draw salaries which they will not earn." It was in San Francisco that the mayor, Schmitz we believe his name was, turned out the Board of Health some three years ago because it persisted in its duty of reporting the cases of plague as they occurred in the city. No wonder, therefore, the *Chronicle* man thinks all Health Boards are the creatures of politicians.

**Adulterated California Wines.**—Examinations by the city chemist of San Francisco have on several occasions revealed adulteration of the wines of the State. Since many physicians depend upon the California wines as the purest that can be obtained, the necessity of submitting them to chemical examination should be understood. In a recent report, it is stated that analysis of 51 bottled and 164 bulk wines revealed the presence of coal-tar dyes in 22 samples, salicylic acid in 14, and benzoic acid in 10. Two samples were said to be so high in volatile acids as to be unsalable as wines. Arsenic was found in 23 samples in quantities ranging from a mere trace to a "quite appreciable quantity," but its presence is admitted to have been entirely accidental. An investigation will be made into the manner in which the arsenic got into the wine, but the San Francisco Health Board, it is said, has no authority to condemn or destroy adulterated goods.

**A Fraudulent Formula Company.**—A San Francisco concern doing a curious business has been refused the use of the mails by the issue of a "fraud order." The firm is said to have advertised to physicians many prescriptions of rare merit at various prices, but sent to the innocents who remitted money only such formulas as they could have obtained from their textbooks.

**The Canadian Medical Association** held its annual meeting in Halifax on August 22, 23, 24, and 25, under the presidency of Dr. John Stewart of that city. The following officers were elected: *President*, Dr. Alexander McPhedran, Toronto; *General Secretary*, Dr. Geo. Elliott, Toronto; *Treasurer*, Dr. H. B. Small, Ottawa; *Vice-Presidents*, Prince Edward Island, Dr. H. D. Johnson, Charlottetown; Nova Scotia, Dr. G. Carleton Jones, Halifax; New Brunswick, Dr. Emery, St. Johns, Quebec; Dr. H. S. Birkett, Montreal; Ontario, Dr. J. D. Courtney, Ottawa; Manitoba, Dr. H. P. Prowse, Winnipeg; North-West Territories, Dr. H. C. McKid, Calgary; British Columbia, Dr. R. E. McKechnie, Vancouver. *Local Secretaries*, Prince Edward Island, Dr. Simpson, Charlottetown; Nova Scotia, Dr. J. R. Corston, Halifax; New Brunswick, Dr. J. A. Scammell, St. John; Quebec, Dr. Ridley McKenzie, Montreal; Ontario, Dr. Harold Parsons, Toronto; Manitoba, Dr. J. R. Davidson, Winnipeg; Northwest Territories, Dr. J. Hislop, Edmonton; British Columbia, Dr. W. H. Sutherland, Revelstoke; *Executive Council*, Dr. W. P. Caven, Toronto; Dr. A. A. McDonald, Toronto, and Dr. F. L. M. Grasett, Toronto. At 10 A. M. there was a discussion in obstetrics. The management of the puerperal state was introduced by Dr. Thomas Walker, St. John, N. B., and continued by Dr. H. L. Reddy, Montreal, Dr. A. A. McDonald, Toronto, Dr. Eccles, London, Ont., Dr. M. A. Curry, Halifax, and Dr. D. McIntosh, Pugwash, N. S. The next annual meeting will be in Toronto in conjunction with the meeting at the same time of the British Medical Association.

**Pacific Coast Association of Railway Surgeons.**—The third annual meeting of this association was held in San Francisco during the second week in August, under the presidency of Dr. Morrison. The election of officers resulted in the choice of: *Presi-*

*dent*, Dr. Thomas W. Huntington of Oakland; *Vice-Presidents*, T. C. McCleave of Berkeley, and W. O. Spencer of Huntington, Ore.; *Secretary*, Dr. John P. Dunn of Oakland; *Treasurer*, Dr. Frank L. Adams of Oakland.

**The American Roentgen Ray Society.**—The sixth annual meeting of this society will be held at the Johns Hopkins Hospital, Baltimore, September 28, 29, and 30, under the presidency of Dr. Charles Lester Leonard of Philadelphia. The Stafford Hotel has been selected as headquarters. The program includes papers by foreign as well as American workers in this special department of medicine. Further information can be obtained from the secretary, Dr. Russell H. Boggs, Empire Building, Pittsburg, Pa.

**A Mosquito War in San Antonio.**—The health authorities of San Antonio, Texas, are waging an active campaign against mosquitos, and hope to have the city entirely free of the obnoxious insects before the San Antonio fair opens. The city is divided into thirty-three districts, each one under the direction of a health inspector, whose business it is to note the condition of every house and the surrounding grounds in his district and see that the householders comply with the law in regard to abolishing breeding places and destroying the mature mosquitos.

**The Fifteenth International Medical Congress.**—Final arrangements have been perfected for the trip of the American party to the International Medical Congress at Lisbon, April 19, 1906. The party will sail on Saturday, April 7, on the North German Lloyd steamer *König Albert*, for Gibraltar, visiting Algeciras, Seville, Cordova, etc., spend a week in Lisbon during the Congress, and return to New York, arriving on Wednesday, May 9. This trip may be made comfortably in a first-class steamer both ways, all expenses paid, including board and lodging while in Lisbon, for $300. A number of side trips are being added and tickets will be good returning through Europe if desired, at a slightly increased cost. The list of those who have joined the party up to the present contains fifteen names. It is requested that those who contemplate making the trip communicate with Dr. Charles Wood Fassett of St. Joseph, Mo., as soon as possible, in order to secure desirable berths on the steamer and good hotel accommodations.

**Levi's Iodine Treatment of Tuberculosis.**—Mr. Dunning, U. S. Consul at Milan, has sent a communication to the Secretary of Labor and Commerce concerning the use of iodine in pulmonary tuberculosis as advocated by Prof. Levi of that city. He says he has received numerous letters of inquiry from America, based on newspaper reports, and he thinks it proper to make a statement of what has been accomplished in order that the hopes of consumptives may not be raised too high. The fact seems to be, Mr. Dunning writes, that Prof. Levi has been experimenting for a more or less extended period with iodine, following and extending certain lines of study which for many years have engaged the attention of Italian men of medicine. For a long time it has been a common belief among many Italian scientists that iodine could be used successfully to attack tuberculosis in men and animals. The difficulty has been to get the drug in such form as to render it suitable for injection. Prof. Levi's experiments have dealt solely with this process, and his "secret" lies in the character of the treatment which he applies to the drug. He believes he has discovered the right formula now, but whether or not he has done so remains to be seen. Meantime, he is working toward the ultimate trials of his discovery, and promises to give the world the result of his labors at the earliest possible time.

**Professional Secrecy in Relation to Crimes Against Minors.**—A New York State law which went into effect on September 1 abrogates in part the exemption of physicians from testifying as to what has occurred in the relation of physician and patient. The law provides that if the patient is under 16 years of age and the physician has come into the knowledge, through his relation, that a crime has been committed he will be called upon to testify and will not be exempt, as formerly.

**Yellow Fever at Quarantine.**—A Panama Railroad employee who arrived at this port on the *Havana* on Thursday of last week was found to be suffering from yellow fever and was removed to Swinburne Island. Three other passengers on the same vessel were found to have an elevated temperature and were kept at the hospital under observation.

**Federal Control of Southern Quarantines.**—The matter of holding a general convention of Southern States to consider whether or not all quarantines shall be put in the hands of the Federal Government will probably be held in a short time. A law has already passed placing quarantine restrictions in the hands of the Government, but the Public Health and Marine Hospital Service has refused to take hold of the matter except at the request of the Southern States affected.

**An Investigation of Graveyard Insurance.**—Evidence of extensive fraud in the writing of insurance on risks known to be bad is said to have been brought to the attention of the Amstrong Committee of the New York Legislature which is now conducting an examination into the methods and practices of the life insurance companies of this city.

**The Use of Wood Alcohol** in any preparation is forbidden by a new State law which went into effect September 1. It declares that any preparation containing methyl or wood alcohol shall be classed as adulterated. The penalty for the wilful violation of the health laws of city or State, such as the manufacture or sale of an adulterated article, is imprisonment not exceeding a year or a fine of $2,000, or both.

**Dr. Edmund A. Babler** of St. Louis was the author of an interesting article on the significance of sudden severe abdominal pain, appearing in the *New York Medical Journal*, but credited in our abstract on August 12 to another writer.

**Medical Department of Fordham University.**—The new medical department of this institution will open on September 28 with the following faculty: Anatomy, George A. Leitner; Physiology and Hygiene, E. Franklin Smith; Materia Medica and Therapeutics, Thomas J. Dunn and James N. Butler; Chemistry and Physics, taught at St. John's College; Obstetrics and Gynecology, John Aspell and George M. Edebohls; Neurology and Historical Medicine, James J. Walsh. As only first year work is to be undertaken during the present session, the list of professors is not yet complete. Dr. James N. Butler is Dean of the Faculty.

**Obituary Notes.**—Dr. Sarah B. Flemming, the first woman physician to be graduated from the Syracuse, N. Y., University, died August 19 at her home in Coronado, where she has resided for the past twenty years. She was born in

Bradford, Pa., seventy years ago, and was graduated from the Syracuse University College of Medicine in 1873. She practised medicine in Rochester, Baltimore, and Washington, D. C., and was a member of the New York State Medical Society and of the medical society at Washington.

Dr. Samuel H. Fee of Kingston, Ontario, died August 31. He was a graduate of the Royal College of Physicians and Surgeons, Kingston, in 1862. He served in the medical corps of the Union Army. during the Civil War.

Dr. Henry F. Garey of Baltimore died August 31. He was a graduate of the Washington University School of Medicine, Baltimore, in the class of 1876.

Dr. Charles W. Fordyce, an interne at the German Hospital, Los Angeles, Cal., was drowned while bathing in the Kern river on August 20. He was twenty-seven years of age and was graduated from the Los Angeles Medical School about three months ago.

Dr. Robert W. Hynds of Atlanta, Ga., died of typhoid fever on August 18 at the age of twenty-six years. He was assistant bacteriologist and chemist of the Atlanta Board of Health. He also held the position of assistant secretary of the State Board of Health, and was a member of the staff of the Wesley Memorial Hospital.

Dr. Jared E. Cone of Youngstown, Ohio, died August 24 of rheumatic endocarditis at the age of forty-nine years. He was born in Iowa and was graduated from the Medical Department of the Iowa State University in 1882. He practised for four years in South Dakota and then removed to Youngstown. He was an ex-president of the Mahoning Medical Society and was visiting physician to the Mahoning Valley Hospital.

Dr. George I. Mackenzie of Pictou, N. S., died on August 20 at the age of sixty-eight years. He was a graduate of the Jefferson Medical College, Philadelphia, in the class of 1864.

Dr. Siegfried Martus of this city died on August 31, following an operation for appendicitis, at the age of forty-three years. He was born in Russia and was graduated from the New York University Medical School in 1889.

Dr. M. H. Hardy of Provo, Utah, died suddenly on August 23 of disease of the heart. He was born in Groveland, Mass., in 1844, and was taken by his parents to Salt Lake City in 1852. For many years he was connected with the Mormon schools, but later took up the study of medicine and was graduated from the New York University Medical School in 1885. From 1896 to within a few months he was superintendent of the State Insane Asylum.

Dr. Adolph Schlossstein of St. Louis died of apoplexy August 27, at the age of 64 years. He was born in Bavaria and was graduated in medicine at Wirzburg in 1865. He came to this country in 1867 and began practice in St. Louis. A widow and a son, also a physician, survive him.

Dr. Edmund Wales Holmes died suddenly at Philadelphia on August 28, at the age of 54 years. He was born in Cape Town, Africa, where his father was American Consul. He was graduated in arts from Yale University in 1872 and in medicine from the University of Pennsylvania in 1880. He became a resident physician in the Philadelphia Hospital and subsequently lecturer on anatomy in the University of Pennsylvania. He was one of the surgeons to the Methodist Episcopal Hospital.

# Correspondence.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

PHYSICAL DETERIORATION AND HEREDITY DISCUSSIONS—HOSPITAL SUNDAY FUND—SANITARY INSPECTORS' CONFERENCE.

London, August 18, 1905.

The inquiry into the alleged physical deterioration has provided much copy for the newspapers, and the interest of the public is being accordingly stimulated by much irresponsible criticism. Perhaps the closing of Parliament has opened the door to many communications of social importance. Dr. Archdall Reid has been bold enough to contribute to the *Post* an article on the subject, explaining his views on the effect of heredity, the result being that other medical men have followed suit. Dr. Reid begins by drawing the distinction between "acquired" and "inborn" characters, the former being never inherited, notwithstanding the popular belief, the lattering including variations tending to be reproduced in the offspring. Passing on to rival theories, he remarks that many medical men believe that parental disease, intemperance, want, hardship, insanitary conditions of life generally cause offspring to be degenerate. Others attribute improvement to natural selection and the elimination of the unfit, and degeneration to lack of selection. The logical corollary, not always clearly apprehended, is that the conditions to which parents are exposed do not cause variations. If offspring were made degenerate at birth, natural selection could not effect improvement, while if beneficial conditions improved offspring, degeneracy would not occur under them. Thus the medical and biological theories are incompatible. Proceeding to state his own views, which are pretty well known to our readers, Dr. Reid remarks that lately some thousands of medical men signed a manifesto to the effect that alcohol is a cause of degeneracy. But he says every race is resistant to alcohol in proportion to its past indulgence, just as is the case with diseases and other adverse influences. Slums are no creation of our day. The races longest exposed to them are in no way degenerate. They are rather preeminently capable of living in slums through having become preeminently resistant to their influences. That city families become extinct in four generations he calls a grotesque legend founded on the fact that migration and intermarriage leave no purely urban families for four generations.

The evidence of some medical witnesses at the Committee on Degeneration is smartly criticised by Dr. Reid. The statements of some at Leicester are also examined, and anent the proposal to collect statistics as to the effect of ill-health on descendants he exclaims: "As though these monuments of misdirected industry were not already sufficiently numerous." The medical profession is best equipped for the study of the problems involved, but, says Dr. Reid, "not till it tries to do something more than merely translate popular prejudices into technical terms will it be in a position to labor in this field with effect." To improve individuals he holds we must attend to acquirements, but the race can be improved only by attending to inborn characters—for example, by placing every obstacle in the way of the reproduction of their own types by the intemperate and feeble-minded.

The day after Dr. Reid's article appeared, the *Post* published letters on the subject from Dr. Saleeby and Dr. Harry Campbell, both of whom regard Dr. Reid's book as the most valuable contribution of recent times to the study of heredity, though neither of them endorses all his opinions. If, as Dr. Reid contends, acquirements beneficial to the individual cannot be transmitted, they cannot improve the race. His inference is that they rather tend towards deterioration by increasing the survival of the unfit. On this Dr. Saleeby says that as posterity are infinitely more numerous than the living, their welfare is paramount; and if proper shelter, food, and training cause deterioration, such provision would be improper and should not be supplied lest a worse thing befall the race. But it would be a sorry state of things which forbade improving the individual lest the race suffer. Dr. Saleeby denies that a beneficial environment of the individual entails racial injury, and says cosmic and moral evolution are compatible; so while caring for the halt, maimed, blind, or insane we may forbid them to perpetuate their infirmities.

Dr. Harry Campbell goes a long way in the same direction. Slum-bred people become adapted to their environment, and the assumption that man might become adapted to slum life is not so far fetched as many suppose. In fact, Jews and members of other races are specially adapted to urban life, because they have been town-bred for many generations. He therefore agrees with Dr. Reid that ad-

verse conditions may damage the individual and yet lead to racial adaptation instead of deterioration.

You must not suppose that such views as I have quoted are allowed to pass unquestioned. A great newspaper having opened its columns to the discussion, there would naturally be no lack of correspondents, and the controversy is still proceeding. That "blessed word," evolution, bulks largely in the debate, as does the equally effective word with so many—education. It is held by some that frailty is transmitted for many generations, and that healthy people are not produced under adverse conditions. That adverse influences improve a race is objected to as a mere hypothesis which any gardener or breeder of domestic animals would reject, as also would many—perhaps most—medical men.

Practical botanists and zoologists, it is said, hold Darwin's theory as of doubtful validity, and, after fifty years' experience in the views of evolutionists, find them at variance with the facts of nature. It has lately been shown that Alpine plants removed to the lowlands lose their Alpine characters; for perhaps thousands of years they have inherited these Alpine peculiarities, but these straightway disappear in new conditions. So, perhaps, slum degeneracy might as readily disappear. The death-rate of slum children is high, and that is attributed by some to their heritage. But others say it is the result of conditions we tolerate in our own generation, and appeal to a comparison between these poor children and those of the well-to-do classes.

At a meeting of the Council of the Hospital Sunday Fund a committee's report came up recommending an increase of salary to the secretary and an alteration in the constitution so as to enable the Queen Victoria Jubilee Nurses' Institute to receive a grant. The former recommendation was agreed to with that alacrity which distinguishes public bodies in voting away other people's money. The other proposal was not adopted. The matter had been brought before the committee by a deputation from the institute, who urged that the nurses did first-aid work and rendered help which often diminished applications to hospitals. One member of the council approved the proposal, and would even extend it to other nursing organizations. But it was obvious that this would be to open the door to all sorts of claims, and money subscribed for hospitals ought certainly not to be voted to other purposes. Convalescent homes and cottage hospitals are now included in the list of beneficiaries, and any extension of that list is undesirable; even a curtailment might be more advisable.

The fund will not be closed until October, but the amount already received is £75,000, and it was resolved to distribute £71,466 among 162 hospitals and 60 dispensaries, the awards to be paid as soon as possible.

Yesterday Sir J. Crichton-Browne presided at the second annual meeting of the Sanitary Inspectors' Association. He remarked that though all men, as Carlyle said, were born hypochondriacs, and in all ages swindlers like Cagliastro drove a thriving trade in well-advertised potions and specifics, never until now had health in the aggregate been the object of such public concern. Topics that not long ago were thought suitable only for a medical society are now talked over at dinner tables or in the streets, and he thought that right, as the help of all classes is needed to promote sanitation. He criticised Dr. Maudsley's recent statements on the doubtful value of sanatorium treatment, and attributed a reduction of 25 per cent. in the phthisis mortality to subsoil drainage and other sanitary improvements—which seems a rather inconsequent notion. Though no precautions used to be taken against spreading the disease, he objected to recent views on heredity, which, he said, "lay at the core of things, while environment played on the surface." I hope the inspectors understood this, which is not as transparent as his advocacy of garden cities and land colonies.

---

**Mouth Affections in Typhoid Fever.**—G. B. Hassin and A. Spare report a case of mouth affection in typhoid fever of an unusual degree of severity. The cavity of the mouth reacts more or less specifically to infectious diseases. In typhoid the mucous membrane is dry, the tongue and lips fissured. Sometimes there is some dirty coating and the formation of ulcers. These are generally of small size and superficial. The case described was in a boy eleven years old. The stomatitis was intense, and a mould of the entire buccal cavity was shed, leaving the oral mucous membrane as one large ulcer. The patient was quite unable to talk on account of the pain caused by movements of the mouth. He recovered. Aside from Peyer's patches, the buccal mucous membrane is more liable to attack than any other part of the digestive canal. In this case the Eberth bacillus is believed to have settled primarily and chiefly in the buccal cavity.—*Clinical Review.*

## OUR PARIS LETTER.

(From Our Special Correspondent.)

MARCH OF CHOLERA IN 1904—ALBUMINURIA IN ITS RELATIONS WITH DIABETES—TREATMENT OF CANCER OF THE STOMACH BY PYLORECTOMY—ENDOSCOPY OF THE URETER AND BLADDER—TREATMENT OF CANCER BY DOYEN'S SERUM CONDEMNED BY THE SOCIETY OF SURGERY—ILEOCECAL TUBERCULOSIS—GENERAL ANESTHESIA BY SCOPOLAMINE—SLEEPING SICKNESS IN A WHITE MAN.

PARIS, July 31, 1905.

At its sitting of July 4, the Academy of Medicine listened to a communication from Professor Chantemesse on the progress of cholera in 1904, and its menace of a European invasion. According to the author, the enemy is not far from us, and we must fear that the extension of cholera will reach us. The epidemic of cholera in 1904 began in the Indies, toward the end of 1899 and beginning of 1900; after leaving this focus of origin, the invasion progressively infiltrated the East, in the direction of China and the extreme Orient; the West, in the direction of Arabia and Europe. It is its progress on the route to this continent that is of interest to us. After appearing at Mecca, in Egypt, in Palestine, and at Bagdad, it reached Persia, and installed itself in Teheran, to infect next Transcaucasia, Transcaspia, Anatolia, and the banks of the Volga, where it hibernated until the beginning of 1904. Europe is directly menaced by several routes, and has been overrun at various epochs by epidemics: by way of the Volga (Moscow, St. Petersburg), by way of the Black Sea (Odessa, mouth of the Danube, Constantinople).

The Academy of Medicine received an interesting communication from M. Lancereaux on Albuminuria in its relation to Diabetes, its Pathological Conditions and Different Forms. The author regarded the pathogenic conditions of albuminuria in diabetes as of three kinds: (1) An intercurrent disease (especially tuberculosis). The urine is characterized by the presence of a large proportion of albumin in flocculent form, and hyaline casts. Here there is an epithelial nephritis, absolutely independent of the diabetes, and allied to the general malady. (2) Arteriosclerosis with consecutive atrophy of the kidneys. Here the urine is dense, limpid, colorless, and abundant. These are the signs of an arterial nephritis, which can be diagnosed by the anatomical examination, and which is allied to arthritism. (3) Absence of any intercurrent malady and of arteriosclerosis; the urine is slightly less than normal, and of a little lower specific gravity, high colored, and albumin is usually abundant. It is the third form that merits the name of albuminous diabetes, by reason of its habitual coexistence with diabetic glycosuria, and which, according to the experience of Cl. Bernard, is to be referred to a disorder of bulbar enervation. At the same meeting MM. Poncet and Delore reported twelve observations on cancer of the stomach treated by pylorectomy, with gastrectomy of more or less extent. Among these twelve patients, the authors had eight cured cases, and this proportion of successes demonstrates the relative lack of danger in this operation: resection of the stomach is, then, to be preferred, and should dominate the therapeutics of gastric cancer. Every probable cancer of the stomach calls for a laparotomy at as early a date as possible, and the earlier this is undertaken the better is the chance that it will not be merely an exploratory operation. If there are then no contraindications, the laparotomy will be followed by a more or less extensive resection of the cancerous stomach.

Among the presentations to the Academy of Medicine of published works, it will not be out of place to mention that of Dr. Georges Luys on Endoscopy of the Ureter and Bladder, presented by Professor Le Dentu. The author, pursuing his interesting original researches on the exploration of the urinary passages, has published the first work on the direct examination, by the eye, of the ureteral and vesical mucous membranes, that has appeared in France. The operative technique of ureteroscopy is illustrated in its different periods by a series of typical pictures, so that the physician, after having consulted this work, will be perfectly prepared to make use of the ureteroscope and cystoscope for direct examination. We know the advantages of this instrument, which permits of the direct examination, without prisms, of the entire ureter, and the greater part of the bladder, especially its fundus. It also permits of catheterism of the ureters, the treatment of vesical ulcerations, extirpation of small tumors, the extraction of foreign bodies, etc. Ureteroscopic treatment properly so called, as well as that resulting from the examination by the ureteroscope, are described in all their details. This book opens up a way to the majority of general practitioners for the delicate intravesical manipulations, which previously have been possible to only a few.

In December, 1904, the Society of Surgery appointed a commission to study the results obtained in the treatment of the different forms of cancer by the application of the serum treatment of Doyen. This commission, in the belief that its results would enable it to formulate conclusions of value, has presented, through Pierre Delbet, a report, which is summed up here. The commission has examined twenty-six patients, affected by cancer or recurrence of cancer in various organs. In the first group Delbet arranges the cases treated by serum without operation. This group includes two series: (1) primary cancer; (2) recurrences. The results are, series (1), three cases; stationary, one case; evident aggravation, one case; death, one case. Series (2), seven cases: two cases, no improvement, continued grave condition; aggravation, five cases. In the second group the reporter includes primary and recurrent cancers treated at once by serum and operative intervention. This group includes two series: (1) initial cancers, twelve cases: no improvement, three cases; aggravation, nine cases. In series (2): stationary, one case; aggravated, three cases, one increasing very rapidly. To sum up, we find that in the five months of their observations, the commissioners saw no case of improvement. They believe that Doyen has been the victim of illusions, which easily deceive the inventors of methods of treatment, so that they confound their hopes with the reality. Personally Delbet has used the Doyen serum in three cases; the result has always been an immediate aggravation of the growth of the neoplasm. At the next meeting, Kirmesson reported a new case of cancer of the kidney treated without success with the serum of Doyen. Fifteen injections were made, between January 23 and March 20; the tumor continued to progress and the general condition to become worse.

The Society of Surgery also engaged in a long and important discussion with reference to a communication by Routier, on ileocecal tuberculosis. The author reported five cases in which he had operated. Tuffier discussed several points with reference to the operative technique, the diagnosis and treatment of ileocecal tuberculosis. Relative to the technique, he considers that the best method of enteroanastomosis is laterolateral anastomosis, after freshening the two ends of the intestine with the forceps of Doyen. From the point of view of diagnosis, he insists on the difficulties of distinguishing it, even when the parts are in the hands, from an ordinary inflammatory lesion. As to treatment, he believes that the resection should always be carried very high, for it is not rare to find the tuberculous lesions extend some distance along the ascending colon.

At another meeting, in reference to general anesthesia by means of scopolamine-morphine, Monod reported that he has used this method of anesthesia in five cases, and the grave accidents that he observed in his last operation had induced him to cease his experiments, and to return to general anesthesia with the mixture of air and chloroform (apparatus of Ricard), to which he should always have remained faithful. His patient, on whom he had done a cholecystenterostomy, had absorbed besides the dose of scopolamine-morphine, about 50 centimeters of chloroform. Twenty minutes after the end of the operation her respiration stopped and the heart ceased to beat. She remained in danger for several days. He does not know whether to attribute the trouble to the scopolamine, the morphine, or to the chloroform. No such accident ever happened to him while using the mixture of air and chloroform, and he thinks it very probable that it was due to the mixture of scopolamine and morphine.

At the Hospitals Medical Society, Sicard and Moutier made a communication with reference to a case of sleeping sickness in a white man. The patient presented to the society had contracted the disease two years ago in Gambia. At the beginning he had headache, lassitude, and general asthenia. Partial contractures, with epileptiform crises and long torpor were the predominant symptoms of the second period. Finally, the third stage began about three months ago, with a profound sleep of eighteen to twenty hours each day. Irregular attacks of fever and the beginning of sacral gangrene foreshadow the final act. Lumbar puncture showed a very abundant lymphocytosis in the cerebrospinal fluid, and all the signs of an intense meningitic process. The clinical signs were sufficient to eliminate the diagnoses of general paralysis, cerebral tumor, syphilitic meningitis, and tuberculosis, and to determine the diagnosis to be sleeping sickness. The trypanosoma was not found either in the blood or in the cerebrospinal fluid, but it is well known that, in the white race, the examination for the parasite has not always resulted in its detection. Inoculations in animals are of too recent date to be positive in their results.

The Academy of Medicine has suffered the loss of one of its most eminent members in the section of Therapeutics, R. du Castel, at the same time secretary general of the Society of Dermatology and physician to the hospitals. A former pupil of Ranvier, Lasègue, and Potain, du Castel was at first an anatomopathologist and a clinician, until, as a result of frequent attacks of appendicitis, he was obliged to seek in the Hôpital Ricord, and later the Hôpital Saint-Louis, a field of labor less fatiguing than that of general medicine. He published several works on dilatation and hypertrophy of the ventricles of the heart, on cachectic heart, pulmonary sclerosis, etc.

## IS THERE AN ANTITOXIN FOR YELLOW FEVER?

To the Editor of the Medical Record:

Sir:—As things stand to-day, of course, the great treatment in yellow fever is the prophylactic, which aims to prevent inoculation with infectious material by the *stegomyia fasciata*, but even with this great forward step which science and self-sacrifice have made, we must not be satisfied, but strive to find some means by which some benefit can come to patients with otherwise fatal cases of this disease. With the rest (absolute) treatment of Guiteras or the bichloride treatment of Sternberg, out of 1,080 cases of yellow fever reported for New Orleans in the recent epidemic up to August 16, there were 171 deaths, giving a mortality of 15.83 per cent. This is not a high mortality, but if it can be lowered it is our duty to do it.

One attack of a disease may leave the patient indifferent, more susceptible, or immune to a second attack. Some diseases remain latent and induce intercurrent disorders after apparent recovery, but in yellow fever immunity more or less permanent is the rule after one attack. Insusceptibility to disease may be congenital or acquired; the acquired form is natural (by previous attack) or artificial, and the artificial is active or passive. Whether immunity in yellow fever is ever taken up by the conscious memory of protoplasm and carried from father to son, is doubtful. On the other hand, we have the naturally acquired form of immunity from a previous attack of yellow fever, but whether active or passive artificial immunity can be effected, science thus far is unable to say. It is, however, along this line that I would stimulate further investigation.

Natural immunity after an attack of yellow fever does not seem to be the result of a phagocytosis produced either by positive or negative chemotaxis, but is caused in all probability by antibodies (alexins, lysogenic substances, agglutinating substances, or purely antitoxic). The sudden termination of this disease must be the result of the development of immunity, which barrier of defense is a victory on the part of nature. Relapses occuring at times just when immunity would be presumed the strongest, are to be explained possibly by the theory of hypersensibility.

To deal with immunity we must, of course, deal with the specific cause of a disease, and in yellow fever the germ is so small that it has never been discovered. There is every reason to believe, however, that the germ is present in the blood serum of a patient sick with this disease, and though we cannot see it we can believe it to be there, and deal with the medium, the same as if we knew it to be there. Active immunity cannot be produced by filtered toxins alone, as the germ passes through the smallest filter we have, but attenuated and sterilized cultures could be tried. In order to give passive artificial immunity a good trial, it would be of the highest value to be able to use some of the lower animals and thus spare man. Whether animals have yellow fever, I am unprepared to say, but if it has not been found out, it should be speedily determined, not only for this reason, but to prevent spread. The serum of immunized animals should be given a trial, for in studying yellow fever one cannot be other than impressed with the fact that as soon as nature gains the upper hand, there is a great change, and this change does not alone seem to protect the tissues but suddenly disposes of the infectious agent also. We cannot swear that the germ has been disposed of, because it cannot be seen at any time, but the fact that the mosquito must bite before a certain stage of the disease, or blood to be injected must be taken before a certain time in the disease, to reproduce the disease in another is strongly presumptive that there are no germs present or they are rendered inert. For obvious reasons it would be unwise to try to immunize humanity by continued inoculations with small amounts of virulent material, attenuated cultures, or filtered toxins; so this must be done by immunized serum taken from man or a susceptible animal.

At present there is plenty of material on hand in New Orleans to enable a test to be made by injecting serum from those just over the disease into those who are still ill. If volunteers can be had, enough immunized serum can be gotten for a test. This is, of course, only speculative, but the course and action of yellow fever and other things we know about it, fully warrant that such a trial be made.

John W. Winston, M.D

Norfolk, Va.

## BRADYCARDIA AND TACHYCARDIA.

To the Editor of The Medical Record:

Sir:—In the issue for August 26 of your esteemed journal you quote, without comment, from the *Edinburgh Medical Journal* a remark of Dr. G. A. Gibson: "The terms bradycardia and tachycardia are very bad." And you quote also a salad of Dr. Gibson about early Greek writers and Latin meanings. Beware of false prophets; they are bound to create more and more confusion in our onomatology (which is to some extent a regular jargon already). Both terms are, as you know as well as I do, employed by Greek physicians of the present time, and they are very good terms for slow and quick heart. In support of this assertion I could quote Homer and a number of early Greek writers in general. In some German lexicon I find the word spaniocardia mentioned as preferable to bradycardia; this is as "very bad" as Dr. Gibson's araiocardia.

I hope I will obtain a hearing some time, somewhere, to speak to a dignified audience on the necessity of a reform of our nomenclature. Such reform is a necessity exactly as much as the reforms were of Linné in botanical and of Lavoisier in chemical languages.

A. Rose, M.D.

# Progress of Medical Science.

*Boston Medical and Surgical Journal, Aug.* 31, 1905.

**Ulcer and Cancer of the Stomach: Their Relationship.**—C. Graham presents the following conclusions based on clinical experience. (1) The great majority of gastric ulcers are located at the pyloric end. The immediate pylorus comes first, the lesser curvature second. A small per cent. is found elsewhere, few at the cardia. (2) The great per cent. of cancers of the stomach is found at the pylorus and lesser curvature (pyloric end), thatis, the same locations find the greatest number of each. (3) Quite a per cent. (50-60) of patients suffering from carcinoma gives three or more years of a precancerous history. (4) A growing per cent. of cancer cases are found with short histories and ulcer demonstrated as the earlier lesion. (5) A certain per cent., if small, of short ulcer histories leading to acute pyloric obstruction where the ulcer must have been present for quite a period, and latent. (6) Ulcers may be present for an indefinite period and no symptoms follow until obstruction, perforation, and hemorrhage appear, if the acidity is low or absent and the ulcer locates itself along the lesser curvature or near the pylorus. (7) Cancers may develop under the same gastric conditions and only manifest themselves when obstruction or systemic poisoning makes itself felt. The present need in medical practice is the establishment of earlier and better diagnosis of these two conditions.

**Stokes-Adams Syndrome.**—T. J. Foley reports two cases and gives a short résumé of the literature of the subject. Case one was that of a man of fifty-seven years with myocardial degeneration resulting from sclerosed coronary arteries, and Case two, that of a boy of nineteen years, cardiac trouble which may have been the sequel of a throat infection three months before his first attack of the Stokes-Adams symptoms. Case one died while Case two recovered, and at the last examination made appeared to have a normal heart. Concerning the treatment of the condition in general the author says that rest is the most important thing. Diet, tonics, and regulation of exercise are sometimes important. Some of the older patients may live for years but they must guard themselves against bodily or mental worry. This is especially true of the coronary cases. In the developed paroxysms, the cardiac stimulants, like ammonia and the nitrates, are useful. Atropin may be given subcutaneously. The recumbent posture favors the return of blood to the brain. One patient often prevented an attack by getting on his hands and knees and allowing the head to hang down. Cases are known where rest and good feeding caused disappearance of the attacks but without any change of the pulse.

*New York Medical Journal, September* 2, 1905.

**Resuscitation, by Manipulation of the Heart, of a Patient Apparently Dead from Shock.**—The patient of W. S. Conkling was an Italian male aged 47 years who had been stabbed in the chest. After removal some six miles to a hospital he was stimulated by hypodemoclysis strychnine and nitroglycerine and in half an hour was placed under ether, though anesthesia was not at any time complete. There was a long wound running down from the left clavicle over to a point below the right nipple, the muscles being entirely cut through, some of the ribs being severed at their cartilaginous junction, while at each breath a large portion of the left lung would appear outside the chest unless restrained by pads. During the operation the pulse grew imperceptible and the man was apparently dead. A finger passed through a small opening made by the injury into the pericardial sac felt a perfectly still heart. This was seized between the surgeon's thumb and forefinger and manipulated for about a minute when a slight thrill was felt. In presumably five seconds more there was another pulsation from which time the organ gained in strength. Suffice it to say that the patient recovered. While it was impossible to say, in the exciting emergency, just how long the heart was quiescent before manipulation was begun, the author believes the period to have been at least two minutes.

**Some Heart Points for Medical Examiners.**—R. Ellis considers the question from the standpoint of life insurance, insisting that one should consider the conditions respectively of the heart muscle, heart cavities, and blood vessels. A bad heart "pump" with good valves and arteries offers a better prognosis than a good pump with bad valves and arteries. The matter of a murmur or not is of relative minor importance. To study the heart muscle one must keep in mind the signs that nature gives of myocardial changes, due to hypertrophy, dilatation, fibroid, senile, or fatty degeneration. These signs are tachycardia, bradycardia, arrhythmia, cardiac asthma, angina, dyspnea, indigestion, and vertigo. The relative significance of the various murmurs is considered in detail and the common mistakes made in their intepretation are thus summarized: 1. Excited, nervous heart, beating against thin chest walls; diagnosticated as hypertrophy. 2. Loud systolic murmur, widely diffused over left chest and behind, and disappearing with the anemic condition; diagnosticated as mitral regurgitation. 3. A loud mitral systolic murmur clearly heard six months after typhoid fever, miscalled organic mitral regurgitation. In three months such a heart may regain its muscular strength, the dilated mitral orifice may contract to its normal size, and the leak prove to be only relative. 4. Flint's aortic regurgitation heard at the apex miscalled mitral stenosis, though the peripheral signs show the true lesion. 5. Forgetting to hunt for the aortic murmurs at the third and fourth left and second right interspace because the sounds at the apex are clear. 6. Diagnosticating a cardio respiratory murmur heard about the apex, in the axilla, and behind, as mitral regurgitation. 7. A condition in which the apex beat is two inches to left nipple line, a heaving heart, a clear first sound, an intensified second, with tense arteries, miscalled a normal heart. 8. An aortic systolic murmur diagnosticated as true aortic stenosis, when there is a strong aortic second sound, no cardiac thrill, and no low plateau pulse. It is well to remember that there are ten possible causes for an aortic systolic murmur, one of which is aortic stenosis. 9. The greatest mistake of all and often the real cause of most mistakes: Listening to a heart through the clothing—from a thick shirt to shirt, waistcoat, and coat.

*Medical News, September* 2, 1905.

**Medical Treatment of Nephritis.**—According to A. R. Elliott, cases of chronic renal disease naturally fall into two main groups, those with and those without dropsy. When dropsy is absent, we should protect the kidneys from irritation—especially from that referable to intercurrent acute toxemias—and we should maintain cardiovascular compensation. To effect the first, we must carefully regulate diet and personal hygiene. Not too much fluid should be taken. The bowels must be kept open. To effect the second we must regulate arterial tension and vasodilator remedies are generally needed. The nitrates of sodium and potassium, erythrol tetranitrate, aconite, the iodide, etc., are indicated. Early evidence of genuine cardiac incompensation calls for positive action. This need not necessarily consist of digitalis or other cardiac tonics, for rest in the recumbent position, restriction of fluids, and general tonic measures will often restore the working capacity of the heart. Should the derangement of the cardiac action threaten to produce or actually result in dilatation, digitalis is indicated. When dropsy is present, however, it signifies either that the patient has developed diffuse inflammatory renal changes or a dilated heart. For the former, rest in bed, a light milk-farinaceous diet, diaphoresis, and purgation are necessary. Dechloruration is necessary, that is, "little water and no salt." A septic puncture of the legs and scrotum with tapping of the chest and abdomen may relieve the patient. For the dilated heart, rest in bed, digitalis, theobromine, etc., find a rational employment. In the presence of uremic manifestations we should purge freely and cut off all proteid food. Acute cases demand venesection. Enteroclysis is one of our most valuable agencies. Lumbar puncture has recently been recommended. Diaphoresis must be carried out vigorously and persistently. The author declares that under no other circumstances is nature's faculty for adjustment so wonderfully illustrated as in chronic kidney disease. Despite the most serious defects, nature's compromise not only preserves a balance of fair health, but does so for astonishing

periods. A realization of this fact should be a warning to us that nature needs our assistance only, seldom our interference.

**The Care of the Perineum, With a Description of a New Method of Delivery of the Shoulder.**—H. R. Kerr thus describes his method, his patient being at this stage of delivery in the left lateral position at the edge of the bed. As soon as rotation is effected, the left hand is placed on the right side of the child's head and pressed back firmly. There is no danger of doing harm here as the point where the left shoulder presents against the perineum is too high up to lacerate. What does this do? First, it stretches the perineum once more *from its circumference*, laterally and posteriorly, toward the center and anterior. Muscular contraction is thereby almost entirely overcome. The perineum is now temporarily paralyzed and is elastic like rubber and can hardly be made to tear. Second, for every inch or fraction of an inch that the left shoulder can be carried back into the perineum, *we gain that much in* lowering the right shoulder into the pubic arch. Now, when a pain occurs, the left shoulder cannot descend because it is held well back and high up in the perineum. Not so with the right shoulder, which does descend. As it does so, it describes part of a circle around the left shoulder, held at a fixed point high up in the perineum, so that the course of the right shoulder is downward and slightly backward, bringing the prominence of the shoulder well back into the vulvaginal outlet, and the right arm, below the shoulder, into the pubic arch. One pain is usually enough to bring down the right shoulder and cause it to bulge well out of the vulva. This accomplished, the fingers of the left hand, with which backward pressure is being made, are placed low down on the back of the neck or upper end of the spine, which is raised up. This increases the space between the back of the child and the maternal soft parts on the left side below and also opens the right axilla. Through this opening in the axilla the forefinger of the right hand is passed and hooked around the arm, close to the shoulder, bringing it down behind the child's back out of the vulva and sweeping it over the pubic arch. Then, before relaxing my grip with the left hand, the right hand is placed on the left side of the child's head, which by a downward, forward and slightly upward movement is delivered, the left hand in the meantime supporting the perineum.

*American Medicine, September 2, 1905.*

**Study of the Gastric Contents in Urticaria.**—Leonard K. Hirshberg in a study of the gastric contents in eight cases of urticaria seems to have proved the frequent coincidence of hyperacidity with this condition. Five of his eight cases of urticaria, one of which was the gigantic form following tetanus antitoxin injected as a prophylactic, show a high total acidity with high amount of free hydrochloric acid. Dr. Hirshberg has been unable to find any previous analyses of the stomach in urticaria cases, published in the literature. He suggests a further study of these cases by some one who has access to a larger number of urticaria individuals.

**Arteriosclerosis Affecting the Nervous System.**—B. C. Loveland says arteriosclerosis affecting the nervous system would be naturally divided into three or possibly four classes: cerebral, spinal, peripheral, and possibly sympathetic. Cerebral arteriosclerosis may be again divided into a major and a minor type. The major type passes rapidly to apoplexy and paralysis or death, and has few symptoms early in its course. The minor type comprises a complex of symptoms which are the direct expression of the vascular change, exclusive of such accidents as hemorrhage and its consequences. The symptoms include fatigue or exhaustion of the brain; the inability to take up new work, while familiar work can still be done; headache, usually frontal and persistent, increased by stooping and abdominal pressure; slight vertigo, and loss of memory—in fact, the symptom complex so frequently associated with neurasthenia. To this class also belongs that list of degenerative mental diseases. Arteriosclerosis of the spinal cord has the same major and minor types, the former marked by small hemorrhages, paralysis, and rapid degeneration, and myelitis; the latter by the slower degenerations of the cord such as the locomotor ataxia following syphilis. The effect of arteriosclerosis on the peripheral nerves is well illustrated by intermittent claudication. Reynaud's disease, acroparesthesia, and quite a variety of sensory disturbances in the extremities such as persistent coldness, formication, itching or burning sensations, and possibly the neuritis so frequent in gouty diabetes. The effects on the sympathetic nerves are not so easily recognized, but when the arterial trouble can be determined elsewhere such symptoms as cardiac irregularity, some vague nervous sensations associated with digestion, persistent flushing of the skin sometimes associated with albuminuria, may be attributed to this cause. The treatment is the same so far as medicine and diet are concerned as in general arteriosclerosis; the two points which make for the best success are early diagnosis and persistent, continued care.

**Etiology and Diagnosis of Early Tubal Pregnancy.**—William E. Ground during the last ten years has operated in twenty-eight cases of tubal pregnancy. Of these, twenty-one were operated after rupture and seven before rupture had occurred. All prerupture cases were abdominal sections. Of the complicated cases sixteen were suprapubic and five by the vagina. All the patients recovered. All had demonstrable lesions sufficient to account for the arrest of the fecundated ovum in the tube. The results of gonorrheal infection and minor postpuerperal lesions were most frequently noted as etiological factors. Early diagnosis and prompt operation in all cases is necessary to reduce mortality and prevent morbidity. In the vast majority of cases a diagnosis can be made before rupture, when the mortality will be no higher than interval operations in appendicitis. In Dr. Ground's cases 85 per cent. had been seen by one or more physicians before rupture occurred.

**Some Gynecological Superstitions.**—Lucy Waite says that gynecology has been encumbered with numerous dogmatic theories which have been stated and restated so many times that they have been finally accepted by the profession without question, and have become veritable superstitions. She takes up the questions especially of backache and constipation as symptoms supposed to be caused by retrodisplacements of the uterus, and shows by statistics that both of these conditions are present in a large percentage of antipositions, and absent in a fair percentage of retropositions.

In 1,000 cases taken from her clinic at the Mary Thompson Hospital, 44 per cent. of the patients with antiposition and of the cases of retroposition 34 per cent. of the patients with retrodeviation stated definitely that they did not suffer with backache. In 500 cases 52 per cent. of the patients with antiposition gave a history of constipation, and of the cases of retroposition 34 per cent. of the patients reported normal bowel movements. The question of childbearing as a remedy in dysmenorrhea is also discussed. Of 300 patients the question, "Have you more or less pain since the birth of your children?" 45 per cent. reported more pain, 30 per cent. less, and 25 per cent. no difference. Dr. Waite believes that the practical application of the statistics relating to the clinical significance of retroposition of the uterus bears directly on the enormous amount of unnecessary operating which is being done under the false impression that the symptoms of which the patient complains are due to the position of the uterus and the complications which are in reality responsible for the symptoms are overlooked.

*Journal of the American Medical Association, September 2, 1905.*

**Fibroid Growths of the Abdominal Wall.**—C. A. Powers after a brief mention of three typical cases observed by him, gives an account of these so-called dermoid growths and their characteristics, and discusses their etiology, diagnosis, and treatment. He reviews and points out the objections of various theories of their formation, and suggests that, for the cases following pregnancy, the three factors, diverted or superfluous embryonal elements, active proliferation or normal fibrous tissues, and stretching or distension of the parts involved may come into play. In cases from trauma, there is not the stretching, but there is an edematous succulence that may cause a like result, and cases following laparotomy scars and local pressure could also be thus explained. Diagnosis is not always easy, and may require exploratory incision in specially difficult cases. Treatment is purely surgical, and even with the smallest tumors, if situated back of the rectus, may call for peritoneal resection; this contingency, therefore, must be kept in mind. The mortality of the operation, aseptically performed, is slight, but relapses occur in a considerable number of cases. The smaller the growth operated on the less the liability to relapse.

**The Removal of the Pathological Spleen.**—After reporting a case of a successful removal of the spleen, B. B. Davis discusses the functions of the organ, the mortality and indications for splenectomy and disorders that call for it, and summarizes his principal function conclusions in substance, as follows: 1. The more probable function of the spleen is the manufacture of red blood corpuscles, with the strong probability of an internal secretion of value in regulating the relative proportions of the various elements of the blood. 2. Splenectomy is contraindicated in leukemia, amyloid spleen, splenic hypertrophy secondary to hepatic cirrhosis, secondary malignant disease, and in the essential anemias. 3. It is usually preferable so splenoplexy in wandering spleen, which is almost always due to previous hypertrophy. 4. In splenic abscess, if successful drainage is possible, it is better than splenectomy, especially if the splenic tissue is not destroyed. 5. In case of cysts, benign tumors, tuberculosis, and sarcoma, splenectomy is the operation of choice, unless in the three former conditions resection of the lower

extremity of the organ will remove all the disease. 6. In rupture, the organ should usually be removed. The operation should be prompt and expeditious and with every expedient to relieve and to prevent shock. 7. In the severe type of malarial spleen, with failure of any medical relief, splenectomy will often result in cure. 8. In splenic anemia internal medication fails and the only recourse is to splenectomy, as early as possible, while the patient can endure the operation and before incurable complications have arisen.

**The Late Poisonous Effects of Anesthetics.**—A. D. Bevan and H. B. Favill report the case of a girl aged twelve and a half, from whom a gangrenous ovarian tumor with twisted pedicle was removed. The operation was done under chloroform and took a long time and an unusually large amount of the anesthetic. The patient did well until forty-four hours after the operation, when there appeared an acute toxic delirium with rapid pulse, tonic muscular contractions, moderately high temperature, and later, increased temperature, Cheyne-Stokes breathing, irregular heart action and death 110 hours after the operation. The autopsy, by Dr. Hektoen, seven hours after death, showed advanced fatty change in the liver, at the periphery of the lobules, and congestion, etc., of kidneys, spleen, and lungs. The authors give an extended review of the literature of similar cases, and concluded that anesthetics, especially chloroform (ether to a very limited degree), can produce a destructive effect on the liver and kidney cells, and on the muscle cells of the heart and other muscles, causing fatty degeneration and necrosis, very like that occurring in phosphorus poisoning. The most constant and important injury is that to the liver, and is in direct proportion to the amount of anesthetic used and the length of the anesthesia. Some individuals appear to be specially susceptible to these effects, and certain conditions, such as age—the younger the patient the greater the danger—those lowering the general vitality, various intoxications, exhaustion, lesions involving fatty degenerations, and chronic affections of the liver and kidneys are also probable predisposing causes. As a result of the liver lesions, toxins are produced either from the liver cells themselves or as a result of their failure in their normal eliminative functions, and these may produce a definite symptom-complex, consisting of vomiting, restlessness, delirium, convulsions, coma, Cheyne-Stokes respiration, cyanosis, icterus in varying degree, and usually terminating in death. It is probable that the milder degrees of this poisoning are observed as transient after-effects of chloroform. The condition is a hepatic toxemia, and in the opinion of the authors, as definite a pathologic entity as a pancreatitis with fat necrosis. Acetone, diacetic acid, and beta-oxybutyric acid are by-products, but not essential poisons, in this toxemia. The liver lesion is the one responsible for the symptoms and the fatal result. In the fatal cases, death is almost invariably due to chloroform; ether is seldom the cause of a death of this kind. Hence, chloroform should never be used with conditions such as have been mentioned as favoring this toxemia, nor for very prolonged operations. The importance of limiting the duration of the anesthesia, when chloroform is employed, is especially emphasized by the authors.

**Ossification of the Lower Jaw in Man.**—After reviewing the various statements and opinions as to the bony development of the lower jaw, Prof. E. Fawcett gives the results of his own studies, covering a period of several years and based on a large amount of new material from various sources. His conclusions are substantially as follows: 1. The jaw in its ossification is not so complex as some claim, though still complex, involving (a) Meckel's cartilage at its anterior extremity, (b) the membrane on its outer side, (c) at least one accessory cartilage found in the condyle, neck, and base of the coronoid process. These statements apply to each half of the jaw. 2. In order of sequence, ossification begins, first, in the membrane between the mental nerve and the middle line and extends backward and under the nerve. Next it commences in Meckel's cartilage about the tenth week of fetal life in the region of the mental foramen and gradually extends inward. That part of the jaw, then, between the mental foramen and the symphysis is compound in origin, being partly cartilaginous, partly membranous, not entirely cartilaginous, as Sutton says. Finally, ossification takes place in the accessory mass of cartilage in the condyle, neck and root of the coronoid process at the third month. 3. There are no separate centers in membrane for either the coronoid process or the angle or for the so-called splenial, all these parts being outgrowths, as it were, from the main mass. 4. The inner alveolar border is developed in two parts by ingrowth from the main mass and at two different periods. The part behind the mental foramen appears first and elongates from before backward; that in front of the foramen appears later and grows from behind forward. 5. The canal for the nerves is completed by the growth of spicules from one alveolar border to the other, over the top of the nerves, the mental nerve being first covered, then the incisive, and the inferior dental much later. 6. The teeth sockets ossify rather late, the canine first. 7. Meckel's cartilage becomes incorporated in the jaw anteriorly by the development of upper and lower shelves, which gradually close over it; behind the mental foramen these shelves do not meet, and Meckel's cartilage, therefore, is not included in the jaw, but gradually atrophies to form the internal ligament of the jaw. In an ordinary dissection at the fourth month this ligament can be seen to be independent of Meckel's cartilage.

*The Lancet, August 26, 1905.*

**The Use of Turpentine in Renal Hydatids.**—E. Mackey records the case of a man of sixty years, with hydatids in the urine and occasional colicky attacks, this history having lasted over a period of fifteen years. A tumor could be felt deep in the left kidney region. Under the employment twice daily of fifteen minims of oil of turpentine, with liquor potassæ, mucilage and liquorice, all his symptoms abated, until finally the hydatids disappeared and there was only a small lump in the region of the kidney. While the author cautions against definite conclusions from a single case, he believes that the remedy deserves a more extended trial in the condition referred to.

**Blackwater Fever Treated with Quinine.**—R. Mowbray reports a case occurring in the northern part of Ireland, this fact showing, according to the author, that any practitioner may possibly be called to such a case. The patient was infected, however, a year or more previously in Africa. Quinine was given in an initial dose of 18 grains followed by 10 grains t.i.d. for five days, and then twice daily for two days more. All doses were given hypodermically. The patient improved rapidly, but on the discontinuance of the remedy suffered an alarming relapse. A renewal of the quinine again brought about abatement of symptoms, and the patient recovered. The author is particularly moved to report the case because there seems to be some doubt in the minds of the profession as to the efficacy of quinine in this form of fever.

**Syphilis of the Third Generation.**—The pertinent facts in the group of patients seen by C. F. Marshall are these: The grandmother has the scars of multiple gummata about both knees. The mother at the age of 16 years had a gumma of the popliteal space and extensive destruction of the palate leading to constriction of the nasopharynx. She married at the age of 19 years and had three children, but no miscarriages. The first child, the case in question (third generation, has distinct saddle-nose deformity and frontal bosses but no other dystrophic stigma of hereditary syphilis. The second child died at the age of three years from "bronchitis"; the third child is said to be healthy. The father was not examined. The possible flaws in the evidence in this case are: (1) acquired syphilis in the mother; (2) reinfection of the hereditarily syphilitic mother; (3) acquired syphilis in the father, and (4) the intervention of another syphilitic genitor. To these objections it may be said (1) In the absence of obvious signs of hereditary syphilis in the mother it is impossible absolutely to exclude acquired syphilis but extensive or advanced tertiary syphilis at the age of 16 years is strongly in favor of the hereditary disease. (2) Reinfection of a hereditarily syphilitic subject with acquired syphilis is known to occur and the immunity conferred by the hereditary disease ceases at about the age of puberty. The evidence in the present case is in favor of pure transmission since the lesions in the child are exceedingly mild and also the mother has shown no evidence of acquired syphilis at any time. (3) Syphilis of the father cannot be excluded as he was not examined; but paternal heredity being apparently a well-established fact, in spite of the recent objections to the theory raised by Matzenhauer, it would be possible for a syphilitic father to beget a syphilitic child with a hereditarily syphilitic mother. (4) The same would apply to another syphilitic genitor in the case of the husband being free from syphilis. The possible intervention of another genitor is always a stumbling block in the elucidation of the problems of heredity, for although a child is obviously the offspring of his mother, paternal parentage is usually incapable of scientific proof.

**The Condition of the Blood Vessels During Shock.**—J. D. Malcolm says that we must rid ourselves of the notion that a fall of blood pressure is an absolute indication of vascular dilatation. On the contrary, other things being equal a contraction of an individual vessel always reduces the pressure within that vessel and the effect on other parts of the vascular system is not invariably the same. He submits the following scheme as to the happenings in the blood vessels during shock. An injury to a nerve causes a contraction of the arterioles throughout the body. If the irritation is sufficiently severe and persistent the contraction tends to increase and to extend to larger vessels as long as the irritation is in action or as long as the operation continues. The radials may become so small that they cease to be felt. From this time onward there is no pulse palpable at the wrist unless the condition of the patient improves. At first the pressure in the carotids is also raised, but after a time

the blood is forced into the central warmer parts of the body, the vessels in which probably relax on account of the physiological necessity for a conservation of heat, and a distribution of blood similar to that found during the digestive process is brought about with a lowered pressure in the carotids and an increased pressure in the portal system. The veins of the internal parts are possibly enlarged rather more than the arteries, but there is no loss of tone in any portion of the vascular system, the evidence being that the arterioles are contracted throughout the body. If the vessels in the splanchnic or in any other large area, or if the veins lose their tone death must follow, as if from hemorrhage. The bulk of the blood is found in the internal veins after death from shock; but this is a post-mortem change, or the blood flows into the veins as the patient is dying.

*British Medical Journal, August 26, 1905.*

**Rats in Relation to Plague.**—Bruce Skinner, from the consideration of the time of year at which bubonic plague is prevalent in different countries and the observed habits of rats, deduces the conclusion that the rat is not the cause of the spread of plague, but is only, like man, a sufferer from the disease. There is some common cause of plague, which is not in constant action in India, although it has been of frequent occurrence in some parts of India. He thinks we should do better to try and discover this common cause, rather than to expend useless energies on trying to exterminate rats, which are of considerable use as scavengers. The prevalence of plague in former times in England, and at present in India, seems to be coincident with the season of year when the rat lives out in the fields, while during the time when he inhabits houses the plague is less frequent. The rat certainly cannot be the cause of the disease, since we know that epidemic diseases are never caused by animal life. There are other effective means besides the destruction of the rat to prevent his living in houses. The rat has a very sensitive foot, covered by a very delicate integument, which is burned by unslacked lime. If we sprinkle the holes and runways of the rat with unslacked lime he will desert our houses. He is also a very thirsty animal, and if we cut off his sources of water he will desert the region. We should use these methods of keeping the rat out of our homes, rather than wholesale destruction of the race, which will not destroy the real cause of the disease.

**False Hay Fever.**—N. Bishop Harman directs our attention to a cause of an affection that simulates true hay fever, which has not been generally recognized among the profession. This is eye strain. He finds that in cases of astigmatism, in combination with strong light, attacks of sneezing and choryza are produced that very much resemble hay fever. It is noted that such attacks will come on in a patient who has one astigmatic eye, beginning in that eye and that side of the nose. Several such cases have been entirely relieved of their hay fever symptoms by the wearing of proper astigmatic correction.

**Lime Water in the Treatment of Warts.**—J. Burdon Cooper accidentally learned that lime water taken internally is almost a specific for warts. When taking lime water for some digestive disturbance, he found that a wart that had been troublesome, disappeared from his finger. He tried this remedy in other cases of warts, and found that the warts disappeared. He recommends the taking of a wine glass of lime water after the midday meal, with a little milk. The wart disappears after from four days to three weeks.

**The Possibilities of Tubal Pregnancy.**—R. Earle Newton reports a case of double tubal pregnancy because of the rarity of this condition. The patient had suffered from puerperal infection six years previously, and had never borne any children since, but had been subject to severe inflammatory attacks and to protuse and frequent menstruation for some years. After missing one period she suffered from pain in the left iliac region, and less on the right side. The lower abdomen was very tender, and a tender, fluctuating mass could be felt, inseparable from the uterus. Operation showed a ruptured tubal pregnancy on the right side containing a fetus a month old. On the left was a mass of old blood clots and a ruptured tube, distended with a blood clot the size of a hen's egg. No trace of fetus could be found, but the tube wall showed decidual cells when examination by microscope was made.

*Berliner klinische Wochenschrift, August 14, 1905.*

**The Induction of Abortion in Cases of Hyperemesis and Tuberculosis.**—Ruge discusses the indications for the interruption of pregnancy in various pathological conditions. No question can attach to the necessity for this procedure in the presence of uterine hemorrhage. In cardiac disease, including affections of the myocardium and cardiac neuroses, only a progressive increase of symptoms justifies the sacrifice of the child. In renal disease, on the other hand, no hesitation is permissible, since not alone may the nephritis become chronic, but the more immediate danger of eclampsia must also be considered. The recurrence of gastric hemorrhage, especially if ulcer has been present at some previous period, as well as the onset of chorea, are both indications for the prompt induction of abortion. In cases of tuberculosis in the mother Ruge recognizes two groups in which pregnancy must be terminated, viz., in incipient tuberculosis, when a complete cure may be looked for, and in advanced tuberculosis, when the pregnancy inflicts too great suffering upon the mother. It must be remembered that a tuberculous mother may give birth to a child that will grow up healthy. Emesis offers an indication for the induction of abortion only when the mother's general condition becomes alarming. Each case must be treated individually, no general rules can be formulated. A high degree of emaciation is not inconsistent with a good general condition. Ruge lays stress upon the evacuation of the bowels and the administration of nutrient enemata with which the patient's strength may be maintained for a considerable time. When this form of treatment must be abandoned abortion becomes inevitable. The author does not incline to the theory that hyperemesis is a manifestation of hysteria.

**Two Cases of Congenital Paresis of the Inferior Rectus Muscle; One Cured by Operation.**—Gutman records a case of paresis of the inferior rectus muscle of the left eye in an otherwise normal boy of thirteen years. The eye was drawn upward and inward. External and internal examination were negative. Diplopia was not present. The head was inclined toward the left shoulder, the face rotated slightly to the right. At operation the muscle was found attached 2 mm. further below the corneal margin than normal. The operation that consisted in advancing the tendon resulted in a complete cure. Identical symptoms were present in a second case not yet operated upon.

**The Chemical Diagnosis of Stomach Contents.**—Bartenstein finds that different portions of the stomach contents removed after a test breakfast vary considerably both in their specific gravity and in their total acidity. Either the first or the second portion may be the more acid. The mean acidity of the stomach contents affords, therefore, no indication of the actual status of the gastric mucosa, since one portion may be secreting a normal gastric juice, whereas another portion simultaneously secretes an excess of acid. Such a variation, the author believes, accounts for the clinical experience that symptoms of hyperacidity may be present, and yet the clinical examination of the gastric contents yield normal results. To secure different portions of the test meal unmixed Bartenstein substitutes for the customary stomach tube a simple suction apparatus in which he introduces a bottle.

*Münchener medizinische Wochenschrift, August 15, 1905.*

**The Successful Inoculation of Rabbits with Foot and Mouth Disease.**—Siegel inoculated a series of rabbits subcutaneously with epithelial scales and the underlying papillæ obtained from the vesicles of cattle infected with this emulsion of the blood and kidneys of two of the rabbits, some of which died after one or more inoculations. An emulsion of the blood and kidneys of two of the rabbits, each of which had been injected twice, was injected intraperitoneally into a young pig, while the livers were given to the animal to eat. Five days later typical lesions of foot and mouth disease appeared. Vesicles removed from this pig were injected into the peritoneum of a second pig, the liver again serving as food. The same lesions manifested themselves here also, but an attempt to transmit the disease to a third animal was only partially successful. Flagellate cytorrhyctes were found in the blood of both rabbits and pigs, sporulating forms occurring in the latter. As the best stain for the entire group of cytorrhyctes Siegel recommends Grenacher's hematoxylin followed by azure II. (1-1000), differentiated in acid alcohol (1 per cent.) and absolute alcohol respectively. Giemsa's stain yields the best results for the flagellæ. The author warns against confounding the cytorrhyctes with the products of plasmorhexis and plasmoschisis and with hemoconien. The latter can be distinguished from the organisms by their smaller size and by the absence of a nucleus.

**An Obscure Case of Disease of the Lymphnodes.**—Möbius reports a hitherto undescribed symptom-complex in a woman aged 57 years. Previous to this illness the patient had only had malaria and migraine. One sister died of Basedow's disease. The patient presented the symptoms of malaise, emaciation, and cardiac palpitation. Physical examination revealed nothing abnormal but a moderate enlargement of the cervical lymphnodes. These symptoms remained unchanged for some time under indifferent treatment, but with the administration of potassium iodide they became markedly intensified, especially the malaise. The cervical nodes increased considerably in size. Later the axillary and inguinal nodes also became enlarged, and psychic disturbances manifested themselves. With the withdrawal of the iodide these symptoms gradually abated

during the ensuing year, the tachycardia and mental weakness remaining, however, until the death of the patient from cerebral hemorrhage twelve years later. During this period a slight enlargement of the lymphnodes of the neck also persisted. Autopsy revealed arterial atheroma and a cerebral hemorrhage alone. Histologically the enlarged lymphnodes were normal. Etiologically Möbius believes this symptom-complex to be due to a toxin elaborated in the body, analogous to, but not identical with, that of Basedow's disease. He emphasizes the similarity of symptoms in both conditions, although the so-called cardinal symptoms of the latter with the exception of tachycardia were absent. In this case, as in exophthalmic goiter, iodides exert a baneful action. Swelling of the cervical lymphnodes is known to occur in Basedow's disease. The writer suggests that the toxin may have arisen from the thyroid, yet exerted an action upon remote organs alone, or from the lymphnodes themselves. At present the latter are not known to possess an internal secretion.

**Stomatitis Ulcerosa and Angina Vincenti.**—Morian reports four cases of ulcerative stomatitis in all of which the bacilli and spirillæ of Vincent were present in scrapings from the ulcers. The ulcers involved the mucous membrane of the cheek alone in three cases, and were single. In the fourth case multiple ulcers were present on the mucosa of the cheek, the tonsil, gums, and the edge of the tongue. The ulcerative process varied in severity from a superficial croupous inflammation to an ulceration so extensive that noma was at first suspected. Abrasions due to carious teeth seemed to have opened a portal of entry for the bacteria in the buccal mucosa. Local symptoms are fetor ex ore, slight swelling and infiltration of the skin of the cheek over the ulcer, and enlargement of the cervical lymphnodes. Constitutional symptoms are absent. Therapy, consisting of disinfection of the mouth, exerts no apparent influence upon the course of the disease. Three of the cases cited occurred in the same institution, the fourth came from an asylum in which other cases were under treatment. Morian concludes that the disease is contagious, and urges isolation of the patients.

*Deutsche medizinische Wochenschrift, August* 17, 1905.

**Are Toxins Ferments?**—Liebermann, as results of experiments conducted with ricin and abrin, answers this question in the negative. A ferment is characterized by its ability to influence a chemical reaction without itself taking part in, or being primarily changed by the reaction. To these conditions the above substances do not answer. In certain constant proportions abrin or ricin added to a suspension of erythrocytes in saline solution will agglutinate the blood cells, but are themselves united to the cells, losing further power to agglutinate. If more of such a suspension of red blood cells be added to this agglutinate mass, no further agglutination will take place unless there is an excess of the abrin or ricin. A ferment occurring either with the erythrocytes or with the ricin or abrin, yet not identical with either may therefore also be excluded. Added to red blood cells in just sufficient quantity to agglutinate the number present, abrin wholly and ricin partially loses its general toxic action. Liebermann supposes an agglutinin and a general toxin to be present side by side in the ricin, acting independently of each other. These substances differ from ferments also in their resistance to prussic acid and to high degrees (65° C.) of heat. The loss of power of toxins after their union with body cells is further shown by the injection of diphtheria toxin into pregnant animals. If less than the lethal dose be injected the fetuses will not show the effects of the toxin which unites with the cells of the mother's tissues, and is thereafter incapable of further toxic action. The writer explained the marked effect of toxins in minute quantities by supposing either that they unite by selective action with cells that are of great physiological importance or that they destroy certain substances essential to the life of the organism. Such substances may be ferments, or ferment-like products of internal secretions.

**The Transplantation of Carcinoma from the Human Female into Dogs.**—Lewin implanted in the abdominal wall of a dog tissue obtained from an ovarian carcinoma characterized by its extensive metastases. Three and a half weeks later the dog was killed. Autopsy revealed a small tumor projecting into the peritoneal cavity from the abdominal scar, numerous grayish-white miliary nodules on the mesentery, omentum, and diaphragm, and enlargement of the retroperitoneal and retrosternal lymphnodes. Histologically the tumor and nodules consisted of accumulations of small round cells, a few leucocytes and large vesicular (endothelial) nuclei. The latter assumed an alveolar arrangement, lying in groups in a fibrous stroma in the tumor of the abdominal wall. The lymphnodes showed acute inflammation. The tumors contained blood vessels, but no necroses were found. Two other dogs were inoculated intraperitoneally, one with fragments of the peritoneum, the other with a retrosternal node obtained from the first animal. In the former, killed after ten weeks, pathological lesions identical with, but more extensive than those described were present. Histologically also the tumors reproduced themselves, but the vesicular nuclei were more numerous, and their alveolar distribution more pronounced. The third animal was subjected to exploratory laparotomy alone. The gross lesions were identical with those found in the other experiments. In no instance was there a reactionary inflammation about the tumors. From the absence of such reaction, from the regularity with which the tumors could be inoculated at will, always maintaining an identical structure, the writer concludes that these neoplasms are either infectious or granulomata or so-called blastomata, and are not due to chemical or physical irritation. Lewin is inclined to group them under the blastomata, since both bacteriological examination and the intraperitoneal inoculation of tumor particles into other animals gave uniform negative results.

**Metatarsus Varus.**—Helbing describes an acquired and a congenital form of this deformity. Acquired metatarsus varus may be due to a compensatory deformity in genu valgum, to fracture of the first metatarsal bone, or to acute or chronic inflammation in the first tarso-metatarsal joint. Whatever the cause, the deformity is constant, and involves the metatarsus alone, the tarsus remaining in the normal position or even being slightly abducted. Simultaneously the great toe becomes fixed in a position of adduction (varus) and plantar flexion. The congenital form is rare. The tarsus is abducted, the metatarsus and great toe assume the varus position, and are flexed toward the plantar surface of the foot. The distal ends of the metatarsus are very prominent. Treatment consists in forcible manual correction with division of the flexor tendons of the great toe if necessary. Where subluxation of the first metatarsal bone follows this procedure, a wedge-shaped resection of the tarso-metatarsal joint may be indicated. In the compensatory form in genu valgum treatment directed to the primary condition may be sufficient to effect a cure.

*French and Italian Journals.*

**Cataract Resulting from a Stroke of Lightning.**—D. Verhaegue has collected from literature twenty-two cases of cataract resulting from the action of lightning. These lesions are not caused by the light, *i.e.* either heat or chemical rays, but by the passage of the electric current. If they were the result of the light they would be found as the result of the action of ordinary electric illumination. Troubles caused by lightning may involve the cornea, lens, or ocular fundus, or produce motor paralyses. The lesions of the crystalline lens are most frequent. The opacity of the lens may begin within a few days after the stroke of lightning, or in a few weeks, or it may be delayed in its appearance for some months. Such cataracts are a long time in maturing so as to permit of successful operations. The author's case had no bad effects until six months after the stroke. The lesions were bilateral. They were three years in maturing, and at one time there was a long period in which the process was entirely stationary. The operative results were excellent. These effects may be the result of the chemical alteration of the histological elements of circulatory changes in the anterior segment of the eye, or of the mechanical action of the current. The author believes it impossible to state by which of these agencies the effect is produced; perhaps the different kinds of electric action are combined.—*Gazette des Hôpitaux*, August 8, 1905.

**Foreign Bodies In the Appendix.**—Schlumberger describes foreign bodies as comparatively infrequently found in inflamed appendices. More often fecal concretions are found in the appendix, the center of which may or may not be some small foreign body around which salts have been deposited, or the appendix is found entirely empty. The author reports the finding of a pin in the appendix of a patient operated on by him. According to the latest researches, among 3,337 cases of appendicitis, sixty-eight foreign bodies were found, that is in 2 per cent. of the cases they were present. The cecal orifice of the appendix may act as a sort of valve to prevent the entrance of foreign bodies, or its peristaltic movements may push them out when they have entered. The foreign substances found are all sorts of seeds, nuts, and bones of fish, as well as bristles of tooth brushes, and pins. Of these the most important are those that are pointed, so that a wound of the appendix may be produced by a blow on the abdomen, or irritation may open a way for the action of microorganisms. In general foreign bodies do not produce symptoms of appendicitis. They may remain latent for a long time, yet they constitute a danger, since they may cause erosions which give entrance to microorganisms. The bacillus coli is constantly present in the appendix, and the diplococcus of pneumonia as well as streptococcus and staphylococcus are the cause of mixed infections in the organ.—*Gazette Médicale de Strasbourg*, July 1, 1905.

# Book Reviews.

THE SANITATION OF A COUNTRY HOUSE. By Dr. HARVEY B. BASHORE, Inspector for the State Board of Health of Pennsylvania, Author of "Outlines of Rural Hygiene." With sixteen illustrations. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1905.

THIS little book is full of practical suggestions for those living or expecting to live in the country or the small town unprovided with a public water-supply, sewers, and other more or less hygienic conveniences. The work has perhaps an even greater interest for city dwellers, for, as has been so often demonstrated, the typhoid fever of cities comes in large part from the country, and the sanitation of rural districts is therefore of the utmost concern to the urban population. In addition to rules for the guidance of those who have a settled habitation in the country, the author has a chapter devoted to "The Summer Camp." The other chapters are: "The Location," "The House," "The Water-Supply," "The Disposal of Waste," and "The Surroundings." An excellent book, full of sanitary wisdom clearly expressed.

THE TREATMENT OF FRACTURES; with Notes on a Few Common Dislocations. By CHARLES L. SCUDDER, M.D., Surgeon to the Massachusetts General Hospital. Fifth Edition, Revised and Enlarged. Philadelphia and London: W. B. Saunders & Company, 1905.

DR. SCUDDER'S popular treatise on fractures was first published in 1900, and each year since that time has seen a new edition, each one in some respects an improvement over the preceding. In this edition the text has been modified when necessary, but the change which will be most appreciated by students of the work is the addition of many *x*-ray and other pictures. A work on fractures lends itself very readily to illustration by half-tones from *x*-ray and other photographs, and the author and publishers have made the most of the good opportunities which this fact offered to make a handsome and useful volume. The young surgeon and the general practitioner will find this book a most valuable addition to their libraries.

A TEXTBOOK OF PHYSIOLOGY, NORMAL AND PATHOLOGICAL, for Students and Practitioners of Medicine. By WINFIELD S. HALL, Ph.D. (Leipzig), M.D. (Leipzig), Professor of Physiology, Northwestern University Medical School, Chicago; Member of the American Physiological Society; Chairman of the Section of Pathology and Physiology, American Medical Association, 1904-5; Fellow of the American Academy of Medicine; Member of the American Association for the Advancement of Science. Second Edition, Revised and Enlarged. Philadelphia and New York: Lea Brothers & Co., 1905.

THE feature which especially distinguishes this second edition of Hall's well-known Physiology is the addition of the discussion, in several chapters, of pathological physiology. "To master normal physiology alone without applying its laws to the symptomatology of disease is," the author maintains, "to miss a large part of the service which physiology should render." In attempting to cover this important field, Dr. Hall has introduced subchapters on the pathological physiology of the circulation and blood, respiration, digestion, metabolism, and excretion, and has also incorporated a brief discussion of the subject in the chapters on the special senses and the central nervous system. In other respects this edition differs but little from the first, except where it has been necessary to make changes to keep in accord with the progress of science. Dr. Hall's work has been a favorite with students of physiology from its publication six years ago, and this good opinion will be only heightened by the appearance of this new edition.

NOTHNAGEL'S PRACTICE. DISEASES OF THE KIDNEYS AND OF THE SPLEEN. HEMORRHAGIC DISEASES. By Dr. H. SENATOR, Professor of Internal Medicine, University of Berlin, and Dr. M. LITTEN, Professor of Internal Medicine, University of Berlin. Edited, with Additions by JAMES B. HERRICK, M.D., Professor of Medicine, Rush Medical College, University of Chicago. Authorized Translation from the German, Under the Editorial Supervision of ALFRED STENGEL, M.D., Professor of Clinical Medicine in the University of Pennsylvania. Philadelphia and London: W. B. Saunders and Company, 1905.

IN many respects this is one of the most satisfactory volumes of the Nothnagel series that has as yet appeared. The original text of Senator's monograph on renal diseases has been regarded as an unusually satisfactory exposition of this subject, and Litten's contributions on splenic and hemorrhagic diseases are equally authoritative. In addition, the American editor seems to have exercised more than usual care in preparing the texts for appearance in English form, and his very extensive additions greatly increase the value of the work. In many cases he has contributed whole sections, such as those on the mosquito in relation to malaria, cryoscopy, and the newer tests of renal efficiency, splenic anemia, congenital icterus with splenomegaly, etc. Other important amplifications of the text contain discussions of the *x*-ray treatment of leukemia, the surgical treatment of nephritis, which is condemned, and of urinalysis. Senator's well-known stand in regard to the existence of physiological albuminuria renders his chapter on that subject especially interesting, but every part of the volume should prove of value to the practitioner. The importance of diseases of the spleen is being recognized with constantly increasing distinctness, and this subject, as well as the one of the hemorrhagic diseases deserves more study than it usually receives.

DIE PALPABLEN GEBILDE DES NORMALEN MENSCHLICHEN KÖRPERS UND DEREN METHODISCHE PALPATION. Nach eigenen Untersuchungen an der Leiche und am Lebenden. Von Dr. TOBY COHN, Nervenarzi in Berlin. I. Teil: Obere Extremität. Mit 2 Abbildungen im Text. Berlin: S. Karger, 1905.

THIS is the first volume of what promises to be a work of more than average interest. While the subject of palpation is to a certain degree taken into account in the ordinary processes of physical examination, especially in regard to bone or joint injuries and in gynecology, this branch of the art has not received altogether the amount of attention it deserves. Irregular practitioners have taken up this neglected subject and have demonstrated its possibilities, sometimes to the discomfiture of wiser men, and it is befitting that it should be established on a thoroughly scientific basis. This task has been undertaken by Cohn, and the first volume of his work, which discusses in most exhaustive fashion everything to be learned by the sense of touch concerning the upper extremity and shoulder girdle, is of a nature to stimulate interest in the succeeding ones.

HUMAN PHYSIOLOGY. Prepared with Special Reference to Students of Medicine. By JOSEPH H. RAYMOND, A.M., M.D., Professor of Physiology and Hygiene, Long Island College Hospital, New York City. Third edition, thoroughly revised. Philadelphia and London: W. B. Saunders & Company, 1905.

THE second edition of Raymond's Physiology, which appeared four years ago, was practically a new book. The revision to which it was then subjected was so thorough, that this new edition only exceeds it by seventeen pages. The text has been carefully gone over, some necessary changes and corrections have been made, and some important topics have been introduced or more fully elaborated. As examples of new matter may be instanced the paragraphs on Vegetarianism; The Identity of Human and Bovine Tuberculosis; The Movements of the Stomach and Intestines; Cardiac Innervation; The Nutritive Value of Alcohol, and Its Influence on the Excretion of Uric Acid; Hemolysis and Bacteriolysis; Distance; and Ovarian and Abdominal Pregnancy. In the section dealing with Nutrition, free use has been made of the researches and contributions of Chittenden. The volume is a good specimen of a first-class text-book, useful alike to student and practitioner; it is well written, judiciously illustrated, and the reader is neither lost in a maze of theories nor bewildered by a multiplicity of laboratory apparatus and details.

LES KYSTES HYDATIQUES DU FOIE. Par le Dr. F. DEVE, Professeur suppléant à l'Ecole de Médecine de Rouen, Médecin des Hôpitaux. Preface du Professeur R. BLANCHARD. Paris: F. R. de Rudeval, 1905.

THIS small work treats of echinococcus disease. The author first discusses the natural history of the parasite, and then takes up in detail the pathological anatomy, etiology, symptoms, complications, diagnosis, and treatment of the disease. The book closes with a chapter on prophylaxis, and a bibliography.

A PRACTICAL TREATISE ON FRACTURES AND DISLOCATIONS. By LEWIS A. STIMSON, B.A., M.D., LL.D., Professor of Surgery in Cornell University Medical College, New York; Surgeon to the New York and Hudson Street Hospitals, etc. Fourth edition, revised and enlarged. With 331 engravings and 46 full-page plates. Philadelphia and New York: Lea Brothers & Co., 1905.

DR. STIMSON has maintained the modern character of his well-known book by giving due prominence to the *x*-ray as a diagnostic aid in doubtful cases of bone or joint injury. Some of the additions to the text deal with fractures and dislocations of the carpal bones, fractures of the lower end of the humerus in the young, and the operative treatment of old dislocations. The number of illustrations has been increased by twenty *x*-ray photographs and some other figures. The prompt appearance of this edition proves that the well-deserved popularity of the work has not abated.

# Society Reports.

## AMERICAN ORTHOPEDIC ASSOCIATION.

*Nineteenth Annual Meeting, Held in Boston, June 6, 7, and 8, 1905.*

THE PRESIDENT, DR. E. G. BRACKETT OF BOSTON IN THE CHAIR.

FIRST DAY—TUESDAY, JUNE 6.

**President's Address.**—Dr. E. G. BRACKETT of Boston delivered the presidential address, referring to the decided enlargement of the field of orthopedic surgery in recent years. This was a real enlargement and not brought about by encroachment upon other fields of work. Especially was this true of the application of orthopedic surgery to adults. Advances had been made in the pathological and etiological factors associated with rheumatic conditions. The importance of mechanical treatment, of the after-treatment of operative cases, and the value of out-of-door treatment were dwelt upon.

**Surgical Treatment of Tuberculous Bone Lesions.**—Dr. CHARLES F. PAINTER of Boston read this paper, pointing out that in spite of the great amount of literature on the subject, it was difficult to formulate therefrom data which could be used in an individual case. He thought aspiration should be resorted to much more frequently in children as well as in adults, and that the temporary fright and pain given to children were more than compensated for by the satisfactory results obtained. Generally it would be impossible to remove foci of disease and extirpation of the disease was impossible. In children the operative treatment consisted principally in the management of abscesses. He favored the closed method, although he considered it less imperative than in adults. Children tolerated apparatus infinitely better than adults. Manipulations directed toward the correction of deformities following tuberculous joint disease during the acute stage must be performed with great rarity. He advised the following methods if the condition seemed proper for operation. Erasions, whole or in part; excision; amputation; manipulation. Conservative methods should be adopted within certain limits and nature allowed an opportunity to effect a spontaneous cure, under the best possible hygienic and dietetic conditions. The following conclusions were drawn: Joints which have suffered from tuberculous infection in childhood, relapsing in adult life, yield the best result if ankylosis can be secured in a good position. If motion is present together with deformity, deformity should be corrected, provided there are as many as twenty-five degrees of motion. If there is less motion than this, deformity should be corrected and ankylosis secured. If deformity is present with ankylosis, ankylosis should be left alone, and deformity overcome. If there is less motion than above, with deformity, ankylosis should be secured.

**The Early Operative Treatment of Tuberculous Osteitis of the Knee.**—Dr. BERNARD BARTOW of Buffalo reported two cases of tuberculous disease of the inner condyle, with end results, corroborating the value of a method of treatment by extracapsular focal incision, etc., and its advantages as a radical procedure, prior to infection of the knee joints. Each case showed good end results, one at the end of six months, the other at the end of one year. He advocated his method because of the comparatively short time of treatment, the relatively large preservation of motion, the simplicity of the post-operative cure, and the removal of the menace of reawakened activity which lay in an encapsulated focus. He thought his method preferable to conservative methods because it was practically devoid of risk, and without liability to infection of the knee joint.

**The X-Ray as an Auxiliary Treatment in Bone Tuberculosis.**—Dr. F. E. PECKHAM of Providence presented this paper reporting five cases treated by exposure to the *x*-ray. All of them were suppurative cases, and in all every means of treatment had been faithfully tried before using the *x*-ray. In four of the cases improvement was very noticeable from the first, and continued uninterruptedly. In the other one of the series there was some slight improvement at first, but nothing permanent, and treatment was discontinued. He thought two of the cases had certainly been saved from amputation, one a leg and another an arm. All of the cases were regarded as "desperate" and only one was a failure. In the light of his experience he thought the *x*-ray may be of the very greatest assistance many times, even when the tuberculous process proves extremely obstinate to all other methods.

**Limitations of Erasion in Coxalgia.**—Dr. R. TUNSTALL TAYLOR of Baltimore, in line with two previous papers on the same subject, outlined a combined method of treating hip disease. He emphasized the value of the *x*-ray as a means facile princeps in making a diagnosis and outlining the treatment in conjunction with characteristic symptoms, and second, the necessity of using in the after-treatment mechanical measures as thoroughly as if erasion or attempted extirpation had not been attempted. He divided cases of coxalgia into three groups. (1) Beginning cases with small focus within the bone and not encroaching upon the joint. These to be treated by conservative methods of rest, fixation, and traction in the hope that nature will arrest the disease. *X*-ray examinations should be made frequently to be assured that there exists no extension. (2) If extension is found, erasion must be performed if acute symptoms persist. (3) If the case has extensive sinuses, secondarily infected, with bad condition of patient and extensive joint destruction as shown by the skiagraph, nothing is to be gained by erasion or excision. The best plan is to lay the sinuses wide open and overcome secondary infection, leaving the original trouble to conservative methods. The middle class of cases only are suitable to erasion. Erasion is of unquestionable value in properly selected cases, but unwarranted where steady improvement seen from conservative methods. In his experience erasion had yielded the best results in function and length if operated upon within 12 to 18 months of the onset. With disappearance of other symptoms, a secondary cold abscess in the soft parts is no indication for extensive erasion of bone.

Dr. JOHN RIDLON of Chicago reported a case occurring in a practising physician, aged 30, who had had hip disease at 10 years of age. Was treated for 5 years, and for 15 years had been without treatment or symptoms. The *x*-ray picture showed a distinct focus one inch in diameter at the upper portion of the acetabulum in the center of which was a piece of carious bone nearly an inch in diameter. This condition had given no trouble for 15 years. There was no deformity, and all motions were good. He thought this case indicated conservative lines of treatment.

Dr. B. E. MCKENZIE of Toronto said that he had obtained uniformly good results in the treatment of tuberculous conditions of tarsus and ankle by the use of mechanical treatment. He considered the prognosis good in such cases contrary to what has been said in former years. Such cases were treated by use of Thomas splint, a brace to hold foot at right angles to the leg, and the use of iodoform which he believed aided in recovery. The same principles were applied to other joints in the early stages. In advanced cases even, he had never done an excision under 14 years of age. In adults, excision had been done comparatively frequently, when the disease was of long standing, and causing much destruction. The results after excision had been good in the knee cases. The treatment of hip cases had resulted less satisfactorily. In the future he said he would be more disposed to amputate. In the treatment of cases of joint tuberculosis deformity should be exceptional where the surgeon had control of the patient.

Dr. L. A. Wiegel of Rochester, N. Y., said that he had not seen any immediate or permanent remote good results follow early operative treatment of tuberculous foci, and was not an advocate of such a procedure except in exceptional cases. Many cases that on clinical inspection seem admirably adapted to operative treatment, upon incision

are found to be so extensive as to make entire removal of foci impossible. It is not possible in any case to say that all foci had been removed. He wished, too, to speak a word of caution in the use of the *x*-ray. Nothing in the way of favorable influence in these conditions had ever been demonstrated, and he thought it unjustifiable to subject those already debilitated to a dangerous agent uncertain in result and profound in action. He thought it better to adopt conservative methods of treatment, and said the claim made for operative treatment shortening the time was not of great consequence, even admitting the truth of such a claim.

Dr. Henry Ling Taylor of New York called attention to the uncertainty of the interpretation of *x*-ray pictures and the error into which one might fall by relying upon such evidence for determining the question of operation. He had seen one case where the *x*-ray showed conditions favorable to excision. This was attempted and the bone found the seat of a very large number of foci. The result of the operation was bad. He thought the *x*-ray of value only when confirmed by clinical findings. He thought early removal of foci might effect a cure in some cases, but that the number that could be so treated was very small.

Dr. G. G. Davis of Philadelphia said that his experience inclined him toward the side of conservative methods. The difficulty of locating the focus was great, frequently there was mutilation in order to discover the focus, and operation had not obviated the necessity for prolonged after-treatment. In the treatment of mild cases, where erasion might seem to be indicated, and even in those cases more advanced with suppuration, conservative methods would effect a cure. Even those cures ascribed to operative interference were often due to the conservative measures adopted in the after-treatment. He had treated cases with severe acute symptoms by trephining the bone in three to five places with a ⅛-inch trephine. This afforded drainage, relieved the acute symptoms, but did not cure. The procedure had been repeated in some cases. In prolonged cases with sinus formation, he believed in opening the sinus down to the bone, curetting, and dressing with iodoform. He thought Bartow's operation ideal if a diagnosis could be made.

Dr. Galloway of Toronto mentioned two cases similar to those reported by Dr. Bartow, where equally good results had been obtained by constructive methods. He thought operation would be less and less resorted to in such conditions.

Dr. J. E. Goldthwait of Boston said that the preceding series of papers as well as recent writings indicated that there is no didactic treatment for tuberculous bone and joint disease, and that we are coming more and more to study the pathology, and plan the treatment upon the pathology. Tuberculosis in the bones or joints represented an infection, and, like other infectious diseases, might be mild or severe, and of slight or extensive involvement. Our function was first of all to save life with as little mutilation as possible in a given case. Mild cases need not be subjected to prolonged operation. In some cases radical operations were necessary. The operation would depend upon the extent of the disease and amputation might be necessary in some cases. Definite principles of treatment underlay any given case.

Dr. E. H. Bradford of Boston agreed with Dr. Goldthwait and said that American surgeons, who have made the great advances in the study and treatment of these conditions, had for some years been in the period of inquiry and investigation. He thought we had now reached the stage of critical judgment. He called attention to the splendid results obtained by C. F. Taylor, who had based his treatment not on pathology, but upon experience, an experience which demonstrated that in hip cases, for instance, pulling the head away from the acetabulum, prevented the bruising following motion with attendant bad results. He did not believe in the good effects of attempted excision of diseased areas in nearly all cases, for reasons already given, and asked, in addition, how it would be possible in a hip case to excise diseased areas from the acetabulum.

Dr. H. Augustus Wilson of Philadelphia said he had experienced great difficulty in correctly interpreting *x*-ray negatives. One case had been under his observation where the indications for operation as shown by *x*-ray seemed definite. Upon operation it was found that an extra-articular injection of iodoform had given rise to a shadow simulating that produced by softened bone. He was doubtful of the utility of erasion.

Dr. A. H. Freeberg, Dr. Painter, Dr. Bartow, Dr. Peckham, and Dr. R. T. Taylor, also discussed the preceding papers.

**The Practical Importance of Correct Foot Postures.**—Dr. Henry Ling Taylor of New York City in a paper of this title said that the support of body weight is the master function of the foot, and when acting as a support it is of vital importance that the foot posture should be such as to furnish stability and good control of movements, and avoid overstrain. The direction of the foot should usually coincide with the direction in which the body tends to fall, which is forward as a rule, and under ordinary conditions. In standing, weight should be frequently shifted from one side to the other, to avoid undue strain. Typical walking should be with forward directed feet, and typical standing with the weight over the straight forward foot. Conventional military and gymnastic postures of attention, with everted feet, are unsuited to prolonged standing, or as a normal in gymnastic and military exercises. The straight foot is naturally used by children, primitive people, mountaineers, guides, and strong and enduring walkers and runners. Out-toeing is typical of the weak and broken-down foot, and is stiff, awkward, and fatiguing. A slight degree of divergence of the feet in symmetrical standing is usual and probably not harmful. This matter is of such practical importance, that a more serious effort should be made to influence the community in favor of the strong posture in standing and walking. He summarized the effects of foot postures in standing and walking as follows: Toeing out throws weight on the heels; increases pronation; diminishes stability and control, consequently weakens the foot; causes stiff or awkward gait, bad general posture, and fatigue. Toeing straight protects the foot, favors efficiency, gives correct general posture, and diminishes fatigue. Toeing in protects the arch, inner ankle, and inner knee.

Standing. All prolonged standing is harmful. It is least harmful when the base is frequently shifted from one foot to the other. The supporting foot should be straight (in the strong posture), that is, point in the direction in which the body tends to fall, which is usually forward. When standing with the weight equally on both feet, they should not be markedly turned outward.

Dr. E. H. Bradford of Boston said that he had some years ago made an investigation of foot positions, and his findings coincided with those of Dr. Taylor. In Holland he had found the straight foot position, while Londoners toed out. The U. S. Marines now march and stand in the straight foot position. In Boston it had not been possible to get the correct position adopted in the public schools.

Dr. C. W. Wilson of Montreal said that English grenadiers had adopted recently the straight foot position.

Dr. L. A. Weigel of Buffalo said that he had recently observed the foot position maintained by the native population in Jamaica, where large loads are carried upon the head and shoes are not worn, and had found that the straight toe position was the one used. A number of photographs, taken without the knowledge of the subjects, confirmed the statements made.

Dr. R. H. Sayre of New York stated that all practical trainers taught sprinters and runners to toe straight, finding that great speed can be accomplished only in this way.

Dr. Taylor, in closing, presented two drawings of a celebrated classical statue, in the second of which the pleasing lines of the figure were destroyed by change to an out-toe position, and said that the strong position is the useful

position, and also the beautiful position, fully in accord with that shown by the best art in sculpture and paining.

**Spontaneous Fractures with Rickets.**—Dr. Henry O. Feiss of Cleveland, Ohio, by invitation reported a case occurring in a child four years old, presenting all the characteristics of marked rickets, and for purposes of investigation the writer took Röntgen pictures of the limbs, and discovered three fractures in the arms. There had been no history of injury, and the bone fragments were in complete alignment, although they were complete breaks. In a review of the literature he called attention to the report of M. John, who had come across similar fractures combined with rickets. The latter writer considered the condition as an individual disease, because the ordinary rachitic fractures are green stick fractures.

Dr. R. F. Taylor of Baltimore thought that there might be coincident existence of osteomalacia and rickets. He had under observation a child which presented evidences of both conditions. The radius and ulna of one forearm, both femora and both tibiæ had been fractured. In another case there were nineteen fractures with evidences of rachitic changs.

Dr. R. H. Sayre of New York said that he had seen a case where the most careful handling resulted in fractures

Dr. Phil Hoffman thought that very likely the case reported was not one of pure rickets. One case of which he had knowledge at first regarded as rickets under observation for 9 years, was finally decided to be osteomalacia. This was in a female, among whom he considered the latter disease more common.

Dr. C. W. Wilson of Montreal had had a case brought to him for correction of knock-knees, in which the bones of the leg were bent by manual force with the greatest ease. Such a case, he thought, might have had fractures from slight causes.

Dr. Feiss, in closing, said that he regarded the case reported as one of pure rickets, based upon the pathological findings. Osteomalacia has an entirely different pathology.

**Congenital Luxation of the Head of the Radius.**—Dr. E. E. Blodgett of Detroit, Mich., by invitation reported a case of bilateral anterior luxation of the head of the radius, occurring in a girl 15 years of age. Decreased function was first noted when patient was an infant, by inability to hold a lump of sugar in the palm. The chief complaint was a partial disability of each arm, illustrated by inability to grasp objects with the thumb on the upper surface. At one time had sudden pain in left elbow on flexion, which gradually disappeared. The forearms were fixed, in respect to rotary motion, in full pronation. Flexion and extension were free. There was hyperextension beyond the straight line, 10° on left and 20° on right. The space usually occupied by head of radius was vacant. Another case occurred in boy of 6 years of age. Since birth the forearms had been fixed in pronation and extension. Radiographs showed bilateral anterior luxation of radial heads. Owing to the fixation, the disability was great. The upper end of the radius on each side was excised, with some improvement 18 months after, but the patient still grasped objects with thumb underneath.

Dr. L. A. Weigel of Rochester said that it was impossible from a flat picture to tell in what plane the radius was lying, whether behind or in front. The only way to definitely determine this point was to have pictures taken stereoscopically. In the present case there was certainly an overgrowth of bone, but he did not feel sure that a dislocation existed.

Dr. Blodgett in reply, stated that his reasons for believing an anterior dislocation to exist aside from the evidence afforded by the *x*-ray were (1) The head was plainly felt in an anterior position; (2) the place it should normally occupy was vacant; (3) the case conformed as a whole to other reported cases, and (4) the case was analogous, in both the general examination and radiographic appearance, to other cases in which visual demonstration of anterior luxation of the head was afforded.

**Skiagraphic Revelations in Rachitic Deformities of the Legs.**—Dr. Wallace Blanchard of Chicago presented this paper in which he said that the correction of over 700 cases of genu valgum and genu varum by rapid osteoclasis furnished opportunities for many skiagraphic comparisons before and after obliteration of deformities. Corrected knock-knee tibiæ have uncovered bow-leg femurs, thus producing bow legs; conversely, corrected bow-leg femurs have disclosed knock-knee tibiæ, creating knock-knees. These have been designated "transition cases." Unsuspected unilateral coxa vara has been uncovered by correction of unilateral knock-knee. Coxa vara is frequent, but covered by more apparent deformities. A weak epiphyseal attachment caused one epiphyseolysis in the use of the Gratten osteoclast. This was the only case occurring in over three hundred supracondyloid osteoclases. Skiagrams of osteoclases revealed an acute angle at the fracture point, and of osteocampsis a longitudinal line between overstretched and impacted sides. A dark shadow marked the extent and degree of impaction. Skiagrams frequently showed only the slightest shadows after extensive fracturing and redressment.

**A Study of Bow Legs.**—Dr. John Dane of Boston read a paper with this title in which he said that the deformity of bow legs had always been regarded as an outward bowing. The accuracy of this belief he questioned. The question of outward or inward bowing is really a question of what is the proper base line from which to measure. If a vertical line down the shaft of the femur is taken, then the tibia is bowed inwards. This bowing is probably caused by the cross-legged position taken by the child in sitting, before it begins to stand. The action of muscles could not produce such a bowing, because they would of necessity produce an equinovarus. After the tibiæ once curve, the altered statics lead to abduction of the femora and this predisposes to anterior bowing of the shaft and coxa vara.

Dr. H. A. Wilson of Philadelphia said that he would like to know the experience of others with reference to the question of whether or not bow legs is a condition which may be outgrown. His personal experience had been that while a compensating curve might remove the external evidences of the deformity, the curve in reality was increased.

Dr. R. H. Sayre of New York said that he had long noted that the curve in bow legs occurred at about the point of crossing of the legs, but it had not occurred to him that this was an etiological factor. He observed, also, that in cases of anterior bow-legs the curve occurred at the point where the legs projected beyond the lap of the mother, and thought this to be one of the causes. He detailed one case where there had been a spontaneous recovery from bow-legs, but he thought such recoveries rare. In the correction of such deformities he used the osteoclast, except where the curve was close to a joint, when he thought the open operation and chisel better, because the osteoclast produced the break further away from the joint than it should be.

Dr. B. E. McKenzie of Toronto said that it was his custom when a child with bow legs was brought to him under 3 years of age, to instruct the parents in massage and manipulations, and that 90 per cent. of the patients recovered without further treatment.

Dr. Henry Ling Taylor of New York called attention to the inward rotation in bow-legs and urged that after the osteoclasis there should be an outward rotation to overcome this tendency.

Dr. John Ridlon of Chicago said that he had never found it necessary to cut the tendo Achillis, but that he had always been able to correct the deformity of the bones broken, without this procedure. He did not believe that there was any tendency to outgrow the deformity, although in exceptional cases it does occur.

Dr. Phil Hoffman of St. Louis reported the results of a number of skiagrams taken in knock knees. He found always a bowing in the upper end of the tibia, and occasionally in the lower end of the femur.

Dr. Frank E. Peckham of Providence reported a severe case of bow legs in which a spontaneous recovery had been

case of bow legs in which a spontaneous recovery had been made. He does not think it necessary to do a tenotomy of the tendo Achillis in anterior curvature.

Dr. BLANCHARD, in closing the discussion, said that the question of performing a tenotomy of the tendo Achillis in anterior curvature was largely a matter of strength on the part of the operator. Aside from that, however, he thought foot could be held in better position after tenotomy. In early cases he thought spontaneous recovery might occur, but where eburnation was complete and bones solid such recovery would be impossible. The so-called spontaneous recoveries were due more or less to manipulation and massage of mothers. In the opportunity to study 1,000 cases, he had yet to see his first case of non-union. He thought it practically never occurred in this country. Another point he wished to make was that in the abduction of the femur there was a change in the direction of the neck without having coxa vara. The neck of the femur might be nearly horizontal with femur abducted, but when parallel the necks are normal. This might be called a simulated coxa vara. True coxa vara is associated with bow legs in some cases, but less frequently, he thought, than had been indicated.

Dr. DANE thought there were natural corrective tendencies and had seen a number of cases improve without formal treatment. He thought bow legs should be considered an inward and not an outward bowing.

**Conclusions Drawn from a Comparative Study of the Feet of Barefooted and Shoewearing Peoples.**—Dr. PHIL HOFFMAN of St. Louis, in a lengthy paper, written after a study of 186 pairs of feet of primitive people, for the most part Filipinos and native Africans, as well as upon shoe-wearing Africans and Caucasians, reached the following conclusions: The relative lengths of the foot and its component parts are the same in barefooted and shoewearing races. Its form and functions are the same in both, up to the time of shoe-wearing, after which progressive characteristic deformation and inhibition of function ensue. These acquired characteristics are not transmitted to progeny. The naked foot presents peculiar plantar and dorsal skin markings due to function. The height and shape of the longitudinal arch have no bearing on the strength or usefulness of the foot, unless existent lowness in an individual is a transition from an originally higher state. There is no exclusive type of arch, for the normal includes the high, medium, and low. There is no relationship between the height of the arch and the character of gait. While the straight position of the foot is the one generally found among primitive people, the everted position is also found. The normal position of the great toe is one in which a prolongation of its axis passes through the center of the heel. A few years of shoe wearing, as shown by certain African tribes, who have adopted shoes since the Boer war, suffices to induce deformity. Compression of the feet necessary to produce deformity may be entirely painless.

Dr. T. HALSTED MYERS of New York thought that the statement made of primitives that the height of the arch and general shape of the foot are not a measure of symptoms, was equally true of the white races.

Dr. JOHN RIDLON wished to state that all painful conditions of the feet relieved by an arch supporter could not be regarded as cases of flat feet. Such symptoms might arise from a lack of normal dorsal flexion due to a shortening of the calf muscles, or what has been called a non-deforming club-foot.

The paper was also discussed by Dr. H. L. Taylor and Dr. A. H. Freiberg.

**Congenital Absence of Tibia.**—Dr. T. HALSTED MYERS reported this case. (See page 93.)

**The Desirability of Replacing Congenital Hip Dislocation in Infancy.**—Dr. BERNARD BARTOW of Buffalo in a paper of this title stated that the case of reduction and the percentage of anatomical cures increase as the operation is performed more closely to the age when the child should walk. The present lower age limit is arbitrarily placed between the second and third years. Objection to further approximation of the reduction maneuver to the infantile age is based on the difficulty of maintaining cleanliness of the retention dressings. Sufficient importance is not attached to changes occurring in the hard and soft parts during the two or three years following birth. These are elements which increase resistance to reduction and diminish security of replacement and opportunity for anatomical restoration, compared with the lesser pathological changes present at the walking age. The difficulty of caring for the child at the walking age is not a barrier to lowering the age limit. A shorter period of splint retention is necessary and there is probably an increased percentage of anatomical restorations. The cast may be extensively cut away on the lateral and posterior thigh portions, leaving a bridge about three inches wide connecting the pelvic girdle with a girdle encasing the lower third of the thigh. No deficiency of support appears to follow. Several cases were reported showing a period of splint restraint shorter by three or four months than could be safely contemplated at the age of 2 or 2½ years. In five unilateral cases where treatment was begun prior to the second year, anatomical cure was obtained in all. Four of these cases were 16 months or younger.

**A Study of the Anatomy of Congenital Dislocation of the Hip After Manipulative Reduction.**—Dr. NATHANIEL ALLISON of St. Louis, by invitation, presented this paper. The case was one of typical double congenital dislocation of the hip, occurring in a girl of seven years, reduced by the Lorenz method. Four months after operation the child died of tuberculous meningitis, and pelvis was obtained at autopsy. The specimen was carefully studied as to the condition of the muscles, nerves, joint capsule, acetabulum, and head of the femur. The iliofemoral band was short and abnormally strong, and would have offered an absolute resistance to a return of the thigh to normal position. Forcing extension resulted in dislocation. The head of the bone was conical and the neck abnormal. The acetabulum was shallow, triangular in shape, with the base posterior. The anatomical conditions found in this case were compared with those found in the cases so far reported.

Dr. JOHN RIDLON of Chicago said that while theoretically he agreed with Dr. Bartow, practically he could not. His youngest patient had been 17 months, and his experience was such at that time that he decided never to operate on so young a child again. He thought that those who had operated upon patients under two years appreciated that while perhaps it was more easy to reduce the head in the young cases it was more difficult to keep it there than was the case in those older. In the latter cases often when once reduced it stays in place securely. He did not believe that the older cases required a longer period of immobilization. In young children, after as much as ten months in plaster, the head will still slip out of the acetabulum. It is possible that other muscles besides the adductors act as stays to keep the head in place, and that this force is absent in young children. We do not know yet what factors lead up to perfect anatomical results. Doubtless it was easier to replace the head in the young and the traumatism was less.

Dr. H. AUGUSTUS WILSON of Philadelphia thought that while it might appear on the surface that early replacement was desirable, the fact existed that in the inability of the child to walk an important factor in the production of good final results was lost. No two cases were alike, and he thought the procedure adopted should depend upon a study of the individual characteristics of each case.

Dr. BARTOW, in closing, said that his cases were too few in number to establish a precedent. His experience, however, did not correspond with Dr. Ridlon's.

SECOND DAY—WEDNESDAY, JUNE 7.

**Clinical Demonstration of the Pathology and of the Methods of Treatment of Congenital Dislocation of the Hip.**—Dr. E. H. BRADFORD of Boston gave this demonstration at the Children's Hospital, exhibiting a number of

cases and pathological specimens. A machine designed to effect reduction in this condition was exhibited and demonstrated by Mr. R. W. Bartlett of Boston.

**Demonstration and Exhibition by Lantern Slides of Lesions in Chronic Non-Tuberculous Arthritis.**—Dr. E. Nichols of Boston gave this demonstration showing the changes undergone by the bones and cartilages in various forms of chronic conditions. The various processes of thickening, erosion, fibrillation, ossification, and formation of joint mice and osteophytes were illustrated.

**Skiagraphic Demonstration of Bone Changes in Osteoarthritis.**—Dr. L. A. Weigel of Rochester showed a number of skiagraphs showing the changes undergone by bone osteoarthritic conditions.

Dr. Reginald Sayre of New York wished to urge the importance of mechanical treatment in such conditions. He thought that a large number of different names had been assigned to the same process, and very probably a varying number of processes to which the same name has been assigned, just as we have different pathological conditions and a very large number of clinical pictures, so we have a large number of etiological factors which have been assigned as a cause. It seemed to him that one must come to the conclusion that in these conditions we are dealing with an inflammation of the joint and that we have very distinct indications for local protection. He thought this requirement had been largely overlooked. His experience, in a number of cases which he reported, had shown good results from such treatment.

Dr. G. G. Davis of Philadelphia said that the prevention of deformity was of importance in the treatment of this condition. Fixation should be used and sometimes excision. With regard to the use of methods forcibly to break up adhesions, his personal experience was that they reformed with the production of a worse condition than before existed. He believed that oftentimes considerable might be accomplished in the smaller joints, particularly of hands and fingers, and perhaps of elbow and knee, by continued small movements never carried to the point of production of excessive or lasting pain. Pain which lasts was thought to be indicative of a relighting of the inflammatory process. A pendulum apparatus to jog the joint would produce a re-establishment of considerable motion.

Dr. J. E. Goldthwait of Boston thought that distinct advances were being made along the line of bone pathology, and that when the pathology was worked out and associated with the clinical pictures an early classification would be arrived at. What have been considered as types of disease will be found perhaps to consist of stages of the same process. An infection of some sort was considered to be responsible for some of the conditions. In the production of the large amount of fringing of the membrane, bacteria had been demonstrated.

Dr. Nichols, in closing, speaking of the treatment, said that while in the advanced cases the changes were so extreme as to be hopeless, in the early stages fixation and protection, baking and passive congestion might relieve the symptoms and give nature a chance to make partial restoration. In those cases due to infection, opening the joint and the establishment of drainage should prove beneficial. In the extreme cases, with destruction of cartilage, eburnation and dentition of the joint, excision for the relief of pain might be a justifiable procedure.

**A Report on the Adult Ward for Women in the Hospital for Ruptured and Crippled for Two Years Ending March 1, 1905.**—Dr. V. P. Gibney of New York in presenting this report commented upon the increased extent of orthopedic work in its application to adult life. The Hospital for Ruptured and Crippled had gone on for forty years without a ward in which those above 16 years of age might be treated for orthopedic conditions. His present report embraced patients from 15 to 67 years of age. Some of the conditions treated were: Torticollis treated by removal of spinal accessory nerve and some of the cervical nerves, various arthritic conditions, curvatures and fractures of the spine, paraplegia, fractures and dislocations of the hip, various acute and chronic conditions of the knee, anterior poliomyelitis, sarcoma of bones, flat foot, hallux valgus, club-foot, and various acute and chronic conditions occurring in the upper extremity.

**Concerning Patterns of the Spinal Curve of Patients with Plaster Jackets for Pott's Disease.—How These May Be Used Without Disturbing the Jacket to Detect Slight Changes of the Curvature.**—Dr. Aug. Thorndike of Boston read this paper and exhibited the apparatus for making measurements. He believed that by the use of this apparatus more careful watch could be kept of the progress of the case. Tendencies toward recurrence of deformity were soon detected and indications for a new jacket made evident. On the other hand, satisfactory progress would be evident and needless changing of jackets with incidental untoward effects avoided. He advocated a modified "hammock" method of applying the jackets as having yielded the most satisfactory results after a comparison with other methods.

The afternoon session was held in the Industrial School for Crippled and Deformed Children, after the members of the association had been afforded the opportunity to inspect the building and the work done in the institution.

**Rigid Spine; A Study, With a Report of Five Cases. Autopsy.**—Dr. Geo. R. Elliott of New York presented this paper and reported two cases of rigid spine of the Strumpell-Marie type, with a report of autopsy in one of the cases. Another case was reported showing the so-called Bechterew type. He suggested that a new classification be adopted, since he believed that many cases were now grouped under one heading, representing entirely different pathological entities, and presented such a classification for consideration.

Dr. J. E. Goldthwait said that he believed that many of the traumatic cases of rigid spine were in reality cases of osteoarthritis, the trauma being the etiological factor in the disease. He believed that pathological investigation would produce a more exact classification. The differential diagnosis was regarded of very great importance in relation to the prognosis and treatment.

**Coxa Vara Adolescentium and Osteoarthritis Deformans Coxæ.**—Dr. A. H. Frieberg of Cincinnati presented this paper in which he saw that since Mueller's description of coxa vara adolescentium (1888) investigation has resolved the condition of bending the femoral neck into a number of components depending upon a variety of morbid processes. Maydl (1897) called attention to the fact that osteoarthritis deformans occurs in juvenile form and may simulate non-symptomatic coxa vara. Pathological investigation has shown this condition as far from rare in youth and requiring it to be taken into account more carefully in the differential diagnosis of coxa vara. The contention that the juvenile form is always traumatic is no longer tenable. Two cases were reported in which this condition came on after adolescence with symptoms precisely those of essential coxa vara. The differential diagnosis was made only by the *x*-ray, which showed the process to be one of yielding of the femoral neck. He insisted upon the importance of differential diagnosis in reference to treatment and ultimate prognosis.

Dr. J. E. Goldthwait of Boston had seen a similar case to those reported with bilateral involvement in which he had deemed osteotomy inadvisable.

Dr. Reginald H. Sayre of New York said that he had seen a unilateral case similar to those reported in which the first symptoms were those of incipient hip joint disease. An *x*-ray examination showed the head and neck porous, a condition which must have existed long before symptoms developed. No deformity was present, but from the condition presented it would almost certainly have taken place later. A protective splint was applied to remove weight bearing from the affected leg.

**Fracture of the Cervical Spine.**—Dr. R. H. Sayre of New York, in discussing this subject, said that fracture of the cervical spine was not necessarily fatal. A number of cases were reported where the results had been satisfactory. The

deformity after the injury resembled that of torticollis. Treatment consisted in rest in bed and the application of the jury mast and plaster jackets, including the head and neck. Patients were frequently allowed to stand upright too soon, with return of various paralyses which are present in nearly every case. If fracture has not united completely, pressure paralyses are apt to be caused in the arms and sometimes in the legs through change in the relation of fragments. These symptoms can often be removed by supporting the head and by degrees restoring the relations of the parts more nearly to the normal. In a certain number of these cases, support can be dispensed with after a time without the recurrence of paralyses. In some cases operative interruption is necessary for a cure.

**Periarthritis of the Shoulder, with Report of Eight Cases.**—Dr. Homer Gibney of New York read this paper. Six of the cases reported were the result of a fall. Three of them were diagnosticated as rheumatism, one as contusion, and one showed evidences of general involvement of joints. Two cases were reported not the result of trauma. Both were treated by breaking up adhesions under ether, application of hot compresses immediately, massage, and use of Paquelin hermocautery. The latter agent he considered very useful as a means of counter-irritation for relief of pain, when used freely. All the cases responded to treatment. He believed that such cases were associated with a circumflex neuritis.

**Multiple Osteoma.**—Dr. G. G. Davis of Philadelphia read this paper, in which he reported two cases of multiple osteoma. One occurred in a man aged 53 years. There was no history of others, members of the family or relatives, having suffered from the same disease. The disease began at 12 years of age. Traumatism was not apparent as a cause. The deformities were of the types of both exostosis and osteophytes, involving one finger, left ulna, both wrists, both humeri, both femora, the left clavicle above the coracoid process, right ankle, and bones of the legs. The patient had a funnel breast and hallux valgus of both feet. The other case reported occurred in a child. The masses were found upon the left fibula at the malleolus, upper third of left tibia, lower third of left femur, right tibia and outer side of fibula, right ulna, right scapula, vertebral border, left scapula at angle, and left humerus. There was beading of the ribs and the epiphyses were all somewhat enlarged. The facial bones were not affected in either case. The paper dealt at length with the various theories advanced, explaining the production of the condition, review of cases so far reported, and various other aspects associated with this condition.

Dr. Henry Ling Taylor of New York said that he had a similar condition to the one reported occurring in three children of the same family. The ages ranged from 6 to 14 years. All were seriously affected with gradually growing tumors, painful in character and deformity producing. The mother had no similar involvement, but the father had a stiffness of the joints.

Dr. H. P. H. Galloway of Toronto had seen a similar case occurring in a patient 18 years of age. The disease began at 9 years of age with growths in the feet and one around the shoulder. These were removed and did not recur, but other enlargements appeared all over the body. They were painless except those situated on the posterior aspect of the leg, which interfered with comfort in sitting. The growths were nearly all situated in the neighborhood of the epiphyseal lines. A brother was similarly affected.

Dr. A. H. Friedberg of Cincinnati reported a case occurring in a boy of 18, who gave a history of a similar affection for three generations. An operation was performed for an aneurysm in the popliteal space caused by one of the growths. Most of the growths were situated near the joints, causing mechanical interference with full movements.

Dr. Dexter D. Ashley of New York mentioned the occurrence of the same condition in a family where the affection was present in four generations.

Dr. L. A. Weigel of Rochester did not consider that the case reported should be considered as one of osteomata, but rather, from the evidence presented by the *x*-ray, should be regarded as one of actual bone disease of the entire osseous system rather than a localized process.

THIRD DAY—THURSDAY, JUNE 8.

Dr. J. E. Goldthwait and Dr. C. F. Painter of Boston gave a clinical demonstration at the Massachusetts General Hospital, of cases illustrative of the various forms of bone and joint disease met with in adults.

Dr. E. A. Codman of Boston, by invitation, gave a demonstration of the surgical anatomy of periarthritis of the shoulder joint with an exhibition of a number of frozen sections.

**An Analysis of 152 Cases of Hallux Valgus in 77 Patients, With a Report Upon a New Operation for Its Relief.**—Dr. H. Augustus Wilson of Philadelphia read this paper. The principal etiological factors in the production of hallux valgus were given as shoes that are too short, those having high heels and pointed toes, and too short stockings and those having pointed toes. These were causative of eversion and pronation of the feet, the greatest factors of all in the production of the condition. Hallux valgus is usually synonomous with bunion, although either may occur independently. An analysis of 152 cases of hallux valgus occurring in 77 patients suffering from this condition out of 397 patients examined, showed apparent exostosis in 141 feet. Radiographic examination did not confirm this finding, since what appeared clinically to be an exostosis was in very many cases in reality the inner and protruding aspect of the distal extremity of the metatarsal bone. In 73 cases there were evidences of external inflammation and apparent bursa formation while in 79 cases there were no such evidences. Observation of the feet in standing and walking showed pronation to exist in 121 feet, while only 33 appeared to approach normal in this respect. Whether this was a result or a cause of the condition under discussion, it was considered as having aggravated the condition. The position of the feet in walking showed 132 feet markedly everted, while 22 approached fairly closely to normal. With such use of the feet the final propulsive spring must fall largely upon that bunion joint instead of upon the great toe. The distinct inactivity of the big toe in the everted and pronated foot constantly tends to produce improper pressure upon the bunion joint. The position of the big toe with reference to the other toes was observed to be as follows: In 14 cases there was no overlapping. In 16 cases there was overlapping by the big toe. In 124 cases there was overlapping by the smaller toes. In 36 feet there was distinct type of plantaris. A large number of *x*-ray pictures were shown to illustrate the pathological anatomy. This was shown to consist in widening of the space between the first and second metatarsal bones, with often a curve in the length of the first metatarsal bone. Displacement in some cases amounting to a partial dislocation at the metatarsophalangeal articulation with projection of the metatarsal bone inward giving rise to an apparent exostosis. Angular deformity of the great toe. True exostosis in some cases. Hypertrophic enlargement of the head of the metatarsal bone in some cases. The operation for the relief of this condition consisted in the removal of that portion of the metatarsal bone projecting inwards beyond the first phalanx, after exciting inflammatory bursæ. The great toe was placed in a normal position by means of a plantar splint with an extension for the great toe. Passive movements were instituted in two weeks, and patients allowed to walk at the end of three weeks. Results in cases reported were entirely satisfactory, with normal function and freedom from pain. Ankylosis resulted in one case only, and that was due to failure on the part of the patient to carry out instructions. Points of superiority claimed for the operation were, unimpaired mobility of the joint, no alteration in the tension exerted upon the tendons of the foot as is the case with linear osteotomy, which increases it, and cuneiform osteotomy which decreases it, and non interfer

ence with the supporting arches of the foot, and the removal of inflammatory bursæ and their cause.

Dr. James K. Young of Philadelphia said that he had obtained satisfactory results in all cases requiring operation by the use of linear osteotomy just back of the head of the metatarsal bone.

Dr. Henry Ling Taylor of New York said that he had used an operation where an oblique bite had been taken off the inner condyle of the metatarsal bone by use of bone forceps subperiosteally. This gave fairly good results, but was not satisfactory. He now took off the whole head of the metatarsal bone by means of an ordinary transverse bite with bone forceps. He did not feel that shortening of the foot thereby produced damage to the arches of the foot, or that the partial ankylosis resulting was of such consequence as to offer serious objections to the operation.

Dr. Charles F. Painter did not think that function was interfered with in the removal of bone by the old method except perhaps in a very few cases. He thought very probably some cases were due to hypertrophy of bone, and that a great many of them were true exostoses.

Dr. Reginald Sayre of New York reported a case of hallux valgus upon whom an operation seemed essential. Abduction of the sac caused rupture of ligamentous bands, and the sac was snapped into excellent position with a loud noise.

Dr. Newton M. Shaffer of New York thought it would be of value to know in how many cases of hallux valgus a contraction of the calf muscles would be found. He believed that this condition was often a factor in the production of hallux valgus.

Dr. Phil Hoffman of St. Louis thought the deformity must always be due to the shoe. However, in most women wearing high heels a compensatory shortening of calf muscles would be found.

Dr. Shaffer said that many of such cases were due to a shortening of the gastrocnemius and were relieved by the application of the traction shoe.

**Demonstration of Machine for Correction of Deformities at the Hip Following Hip Disease, and for Holding the Limb in a Corrected Position While Plaster Is Applied.**—Dr. John Ridlon of Chicago exhibited and demonstrated an apparatus for the purposes set forth in the title.

**Achillotomy and Fasciotomy in a Patient Seventy-two Years of Age.**—Dr. A. R. Shands of Washington, D. C., presented this paper, his object being to show what results may be expected in tenotomy done upon the aged. The patient, aged 72, as result of poliomyelitis occurring in infancy had a partially paralyzed foot with a mild degree of equinovarus. He was unusually well developed and in good physical condition. Under cocaine anesthesia the tendo Achillis was divided subcutaneously and also the constricting bands of the plantar fascia. The foot was placed in plaster of paris in an overcorrected position and so retained for three weeks. The result was entirely satisfactory. There was prompt union of the tendon, and patient could walk with ease and comfort.

Dr. F. E. Peckham of Providence said that he had performed the operation in a patient 70 years of age with satisfactory result.

Dr. Phil Hoffman of St. Louis reported a case in which the limb upon which the tenotomy had been done was found at autopsy, twelve days after operation, to contain no muscular tissue whatever, and all conditions extremely unfavorable for repair, and yet the tendon was fairly well united in this patient of 45 years.

**Investigations on the Value of Traction in the Treatment of Hip Disease.**—Dr. E. H. Bradford of Boston, in a résumé of his paper, illustrated by a number of drawings and models, said that the advantages of traction in the treatment of hip disease had been abundantly shown. The benefit to be derived had been questioned by some writers, and further demonstration of the value of this method would be of use. He assumed that bone affected by tuberculous ostitis might, under favorable conditions, be transformed into a healthy state, and that constant irritation and bruising of the diseased portion of the bony structure was unfavorable to repair and cure. He had examined a number of specimens of advanced hip disease, some of which were old specimens collected by museums before the use of traction in the treatment of this condition, that showed undisputably the forcible crowding of the head of the femur upwards and backwards, leaving the lower portion of the acetabulum opportunity for repair, which had taken place. Corresponding changes took place in the head of the femur when the opportunity for rest was given by the use of traction. Crowding resulted in erosion and destruction. It was manifestly desirable in placing the bone in a condition favorable to repair that this crowding be prevented. That traction could be used so as to prevent such crowding was shown by a series of skiagrams taken with patients suffering from hip disease and subjected to various degrees of traction. The distraction caused by traction was varied in the different stages of hip disease. Traction was often applied in an improper manner and in such way as not to result in pulling the head away from the acetabulum. Such traction should be employed as would overcome the muscular spasm.

Dr. Phil. Hoffman of St. Louis reported a case which had been seen illustrating the tendency in this condition to a crowding and flattening of the joint surfaces. The case occurred in a boy of 11 years of age suffering from hip joint disease who died of meningitis. The specimen showed the disease to exist in the epiphysis of the head of the femur, and the pus had only just burst into the joint, as microscopical examination showed no actual disease of the joint. However, there was a distinct flattening and wearing away of the cartilaginous surfaces.

Dr. Reginald H. Sayre said that he believed in the utility of traction, not only in hip cases, but in ankle and knee cases as well.

**A Study of Thirty Cases of Chronic Non-Tuberculous Joint Disease Occurring in Adults, with Special Reference to Some of Doubtful Identity.**—Dr. Harold W. Jones of St. Louis, by invitation, read this paper considering monoarticular joint lesions of non-tuberculous origin, involving the spine, hip, knee, shoulder, elbow, and ankle. Gonorrhea was the etiological factor in these cases, and syphilis in one other. The cases were divided, for the purpose of study, into (1) cases characterized principally by hypertrophy of the joint, of which there were seven; (2) cases characterized principally by atrophy of the joint, of which there was one; (3) cases of undoubted joint infection, in some of which erosion of the articular surfaces was demonstrated; there were five cases in this group; (4) cases of probable periarthritis, in which infection was at least uncertain and in which no permanent changes in the joint could be shown. In this group seventeen cases were included. In the entire series of cases osseous hypertrophy occurred entirely in the male sex and in the weight-bearing joints. Exposure to sudden changes of temperature and occupation trauma were not found to be an important factor, except in the shoulder, often the seat of disabling joint lesion, where trauma was regarded as an important factor. Moderate success only was achieved in the treatment of the various conditions presented.

**A Portable Frame for Holding a Patient with a Fracture of the Shaft of the Femur while Plaster of Paris is Applied.**—Dr. Frank E. Peckham of Providence in his paper explained and described a frame as above, combining in one frame a number of features found in other devices. One advantage possessed by it was the ability to apply or take off the frame without the necessity of raising the patient from the bed.

**A Modification of the Dollinger Brace for Cervical and Upper Dorsal Pott's Disease.**—Dr. R. Tunstall Taylor of Baltimore read a paper describing a brace which he had used with very satisfactory results not obtained by the use of other mechanical means, the advantages claimed being rigidity, durability, and lightness.

**A Modification of the Back Brace for Pott's Disease.**—

Dr. Aug. Thorndike of Boston read a paper describing a brace to be used in Pott's disease. The apparatus was exhibited and its advantages illustrated.

**Election of Officers and Place of Meeting.**—The following officers were unanimously elected for the ensuing year: *President*, Dr. B. E. McKenzie of Toronto; *First Vice-President*, Dr. C. W. Wilson of Montreal; *Second Vice-President*, Dr. H. P. H. Galloway of Toronto; *Secretary*, Dr. John Ridlon of Chicago, re-elected; *Treasurer*, Dr. E. G. Brackett of Boston.

The association adjourned to meet in Toronto, Canada, at such time as would be appointed by its Executive Committee for the next annual meeting.

## BRITISH MEDICAL ASSOCIATION.

*Seventy-third Annual Meeting, Held at Leicester, July 25, 26, 27, and 28, 1905.*

(Special Report to the Medical Record.)

(*Continued from page* 403.)

### SECTION OF SURGERY.

*Third Day—Friday, July 28.*

**Congenital Dislocation of the Hip and Its Modern Treatment.**—Mr. Jackson Clarke read a paper with this title. He said that Lorenz's method of treatment of these cases was a great advance upon the old operation by the open method, and that the improvement which followed the treatment was greater than that which followed operation. He considered that Lorenz's method was based upon a scientific consideration of the factors upon which success depended. He therefore strongly advocated this method, and thought that it should be followed in all its details according to Lorenz's teaching.

Mr. Jordan Lloyd said that he agreed that this method marked a great stride in the treatment of these cases, but it should be frankly admitted that there was in most cases no real cure effected. As a rule even in the most successful cases treated by this or any other method, the waddling gait and the limping remained, though they were diminished. This should be plainly told the parents before the operation, or much dissatisfaction was likely to result. He considered that no skiagram was of the least use in these cases, for the hand could tell more than the skiagram could show, and further the treatment and method were totally uninfluenced by the skiagram. It was absurd to suggest, as some people did, that one ought to be a specialist to deal with these cases. All that was necessary was courage, though of course the operator must be a man accustomed to dealing with operative and serious cases; and must have given due attention to the technique of Lorenz's method.

Mr. Keetley said that after the patient had reached four years of age the difficulty of obtaining a good result was much increased; personally he considered that many of these cases were simply traumatic, and not congenital at all. Reduction of the dislocation was therefore likely to be followed by marked success. The difficulty in many of them was not the reduction of the dislocation, but the retention of the head of the femur in the acetabulum, which was in some cases partly filled up, and in others but poorly developed, owing to the absence of the head of the femur from it. In these cases he considered that an open incision and the wiring of the head of the femur into the acetabulum gave by far the best result. He passed a wire through the neck of the femur and out again through the acetabulum below the anterior inferior iliac spine. He regarded Lorenz's method as most applicable to very young children, and said that not infrequently it must be followed by an open operation and wiring.

Sir Charles Ball said that the open operation gave no doubt a slight increase of risk, but that the advantage of seeing exactly what were the resisting structures to reduction, and the condition of the acetabulum, with the increased facility for dealing with any troubles that might exist, was so great that he considered the open method was much preferable.

Mr. Jackson Clarke replied that Lorenz was a brave surgeon and not afraid to face the operation by the open method, but he had discarded it as he found the manipulative method better. Many first-rate surgeons on the continent had followed his example and teaching. Lorenz's method was based on the science of the condition; thus, whereas the division of the pelvitrochanteric muscles, which took place in the cutting operation, resulted in their lengthening and a failure to keep the head in its socket after reduction; Lorenz's method of tearing them resulted in their contraction and shortening. He thought that Mr. Jordan Lloyd had been very unfortunate in his results generally. The speaker had as a rule got rid of the limp and the waddling gait and had been able to satisfy the parents.

**Appendicostomy.**—Mr. C. B. Keetley read a paper on this operation, by which he meant stitching the appendix to the anterior abdominal wall and opening it there, so as to make a side entrance to the alimentary canal. The chief indications for its use were mucous colitis, syphilitic ulceration of the bowel, and similar conditions, where lavage of the large intestine was desired. Again in extreme cases of constipation it was safer to perform this operation than to do ileosigmoidostomy. Robert Weir of New York had published the first case of appendicostomy about two years ago. The patient was a girl of 15 years, who suffered from severe constipation and had been 24 days without a motion. After the operation a daily enema through a catheter which was passed into the open appendix was attended by complete success, and a daily motion was in this way obtained, the girl regaining perfect health. Again in some cases of ileocecal intussusception it was quite an open question whether it was not a wise proceeding to fix the cecum to the abdominal wall by the appendix, which might be opened, if thought desirable, at the same time, to leave a safe side entrance into the bowel for use on any future occasion if it should become necessary.

Mr. P. Furnivall said that he had not had any experience of appendicostomy, but that he had on five occasions performed the operation of cecostomy, bringing the cecum to the anterior abdominal wall, fastening it there, and opening it by an incision so as to allow of lavage of the large intestine. The cases were under the care of Dr. R. Hutchinson at the London Hospital, and every effort had been made to cure the condition from which they were suffering, namely dysenteric ulceration, by the ordinary enemata, but without success. After the operation lavage of the large bowel through the cecal opening was speedily successful in each of the five cases. A ¼ per cent. solution of nitrate of silver was used and followed by decinormal salt solution; later a rather stronger solution of silver nitrate was used. He regarded the operation of cecostomy as safer than appendicostomy, and less likely to lead to a permanent fistula, since the cecal wound closed in a few days unless deliberately kept open.

Dr. Howard Kelly of Baltimore said that to some extent he agreed with the idea of the operation, but he thought it extremely likely to be abused. Many of these cases of so-called colitis were not colitis at all, but proctitis, the rectum alone being to blame; he therefore advocated a thorough examination of the rectum, the electric speculum being used if necessary. In the rectal cases it would be absurd to perform any such operation, for proper treatment applied to the rectum was all that was necessary. With regard to the treatment of constipation by this operation, he thought again that in many cases it would be a mistake. Personally he divided constipation into two classes: (1) rectal, and (2) those due to a fault higher up in the bowel. In the former it was quite unnecessary to resort to any operation, for it was due entirely to inertia of the rectum, which was easily remedied by other and simpler measures. He thought there was considerable danger in bringing forward an operation like this which was so liable to be misapplied, and he con-

sidered that the ordinary views upon colitis and constipation required revision and a closer analysis.

Sir Charles Ball thought that if the appendix were ever to be used for anchoring, it would be both safer and better to fasten the cecum to the posterior abdominal wall rather than the anterior. He wished also to ask whether there was not a leakage from the opening of the appendix, which must be very objectionable to the patient.

Mr. Keetley replied that there was no reason why the operation should be misapplied. He thanked Dr. Kelly for his remarks and said that if his paper had produced no other result, he was glad to have read it, as it had led to their hearing from Dr. Kelly his most interesting views upon colitis and constipation. There was no leakage from the opening even of gas, and it was so small that it could not be seen unless the skin folds were drawn aside to show it; at the same time a catheter was introduced with perfect ease for the purpose of irrigation. He quite agreed that the operation should not be used lightly.

**Note on a Specimen of Bladder and Urethra Removed Two Years After Prostatectomy.**—Mr. J. F. Thompson Walker showed a specimen of a bladder and urethra removed from a patient who had died two years after the operation of prostatectomy. It showed that a cavity was left after the removal of the prostate. He also showed some lantern slides of the specimen.

Mr. Barnard raised the question as to whether stricture resulted after prostatectomy, and said that no cases had been published. Undoubtedly a tendency to stricture did exist. He advised removing the prostate in two pieces; the prostatic urethra might then possibly be saved. He thought that after the operation a catheter should be passed every day to prevent the liability of the formation of stricture. The patient should sit up in bed early, say by the fifth day, to enable him properly to empty his bladder; in this way the retention of residual urine and the deposition of phosphates upon the wound and bladder wall would be avoided. It was most important to get the urine as healthy as possible before operating, and he thought there was nothing so good as the acidsodium phosphate, which was the normal acidifying agent of the urine. Patients should be given 3 to 4 pints daily of acid sodium phosphate solution (one drachm to the pint of water), when in two or three days the urine would become acid. With regard to the prostates which should be operated on, it was generally said that the small hard prostate should be left alone; he had operated upon one, and after about $1\frac{1}{2}$ hours hard work he had been able to get away nothing but broken shreds of prostatic tissue, but the patient made a good recovery.

Mr. Jordan Lloyd had heard of a case of Mr. Freyer's where stricture had followed—but Mr. Freyer had not heard of it. He considered it usually due to the formation of a diaphragm across the floor of the bladder owing to the cicatricial contraction of the capsule of the prostate, and he considered that the lantern slides which Mr. Walker had shown gave a perfectly obvious picture of the position in which this diaphragm formed and the manner in which it acted. As a rule, these cases where increasing difficulty followed at some date after the operation, the removal of the prostate had been incomplete, and a residnum of prostatic tissue left behind. He thought it better to remove the prostate working from within the urethra rather than by the ordinary method of enucleating from the periphery of the prostate between the capsule and the gland substance. By this method the gland was peeled off the urethra, which was more likely thus to be left uninjured. This method made it necessary to remove the prostate in two pieces, as Mr. Barnard had suggested. He would like to know what was the lining of the prostatic cavity in Mr. Walker's specimen.

Mr. Walker said that he had shown the specimen, as it was of interest to see the after-results in these cases, but he had not anticipated a discussion upon the whole range of prostatectomy, and he really could not go into all the points which had been raised. He did not regard it as possible to save the prostatic urethra, nor did he think it was of the least advantage to attempt to do so, for if the urethra were saved uninjured it must still slough; since a tube running across a space, such as was left after the removal of the prostate, could scarcely be expected to survive. He did not believe that a diaphragm formed across the floor of the bladder, but in some cases secondary contraction of the neck of the bladder from the formation of cicatricial tissue was apt to occur. The lining of the cavity from which the prostate had been removed in the specimen he had shown was a layer of flattened cells with rounder cells below in the deeper layers, but he could hardly describe it as a true surface epithelium.

**Acute Periostitis and Ostitis of the Spine.**—Mr. A. H. Tubby read a paper on this subject. He said that these cases were generally pyemic; he had seen septic periostitis second to osteostomatitis and double pneumonia. Makin and Abbot had drawn attention to these cases; in one case, which J. R. Hunt had examined bacteriologically, staphylococci were found. The signs of the mischief were tenderness and pain in the supine position; when the neural arches were affected, acute meningitis and acute myelitis might result. The disease occurred most frequently in children and adolescents, occasionally in adults; it was more common in males than in females by 2 to 1. The site of the mischief, as in other inflammatory lesions of the spine, was usually the lumbar region, and then the cervical region, in which it was more frequent than in the dorsal.

**Two Cases of Operation Involving the Surgery of the Thoracic Duct.**—Mr. T. R. H. Bucknall read this paper. The first case was one in which operation was performed for recumbent tuberculous glands of the neck; they were removed and an extensive operation was necessary. The thoracic duct was opened or gave way later, for a large quantity of chyle was poured out into the wound, but this gradually ceased in the course of two or three weeks; no ill effects or interference with nutrition being observed. The patient died some five or six months later from general tuberculosis, and it was an interesting point as to whether or not general infection might have taken place through the duct. The second case was one in which a mass of cancerous glands was removed from the supraclavicular fossa for severe pain due to pressure upon the brachial plexus. The thoracic duct was opened and at once recognized and ligatured; no ill result followed, and there was no impediment of nutrition attributable to interference with the absorption of chyle.

Mr. Barnard said no ill resulted in two cases in which he had ligatured the thoracic duct, and that it had been shown that the thoracic duct had other venous communications than the one opening into the junction of the left internal jugular and subclavian, notably with the right innominate vein, which no doubt accounted for the impunity with which it might be ligatured.

**Sixty-seven Cases of Cleft Palate Treated by Operation.**—Mr. J. Berry read this paper. He said that he performed the old operation and that he thought the new methods of operating by flaps and of fracturing and wiring the superior maxillæ were innovations which had nothing to recommend them, nor to justify their existence. The operation of Fergusson, so ably advanced by Sir Thomas Smith, was far in front of these modern operations. The flap operation of Arbuthnot Lane was said to enable the operation to be performed upon a low arch, where, by the old operation, it was not possible for the flaps to be brought together and the cleft closed. He thought if his hearers would look at one of his cases, which he would show afterwards, they would see that the old operation properly performed could be a success in the lowest of arches. As for the other method (Brodie's operation) which Mr. Edmund Owen advocated, that of fracturing the superior maxillæ so as to diminish the cleft, it was far too severe for these young children and was simply substituting violence for skill. He knew of ten cases in which this operation had been performed in this country; in four it had resulted in death and in one in necrosis; in his opinion it was neither necessary nor justifiable. He consid-

ered that the proper age at which to operate was three years, for after this age the method of speech was rapidly formed, and it was desirable that the soft palate should be repaired and the hard palate also before an imperfect method of speaking was acquired. Some advised operation during the first year; he considered this wrong, because the cleft between the bones tended naturally to close and was very much smaller in the third year than in the first. These operators were gaining great praise because they operated when others refused and apparently with great success, closing the cleft to the parents' great delight; the disadvantages to the child, however, were very great, for the extra dragging of the soft palate to make it inert across the wider cleft of the first year resulted in impaired movement of the soft palate, which made the speech far more imperfect than it would have been if the child had been left for operation in the third year, when the cleft was narrower. Of course the parents did not know this, but he regarded this operating in the first year and the closing of the wider cleft as an attempt to obtain unfair praise at other surgeons' expense. Mr. Arbuthnot Lane, who had suggested the flap operation, said that the reason speech was imperfect in these children was that the air did not pass through the nose during speaking; but, if they compared the speech of cleft palate cases with that of a person suffering from a bad cold, they would find that the consonants which suffered were different, and the manner in which they were uttered was also different, so that it was clear Mr. Arbuthnot Lane knew very little of the condition for which he was devising an operation, and the speaker recommended him to study the matter further. He was absolutely dissatisfied with these new operations; they ought to bring forward more proof of superiority; improved enunciation in isolated cases was not sufficient to prove an advance upon the old operation, which was not necessarily bad because it was old, any more than these were necessarily good because they were new. There was no occasion for a new operation, and he challenged the advocates of these new methods to come forward and justify them if they could. He afterwards showed ten patients upon whom he had operated.

Mr. Cuthbert recommended that too much sponging and handling of the flaps should not be indulged in. He considered the old operation a most successful one.

Mr. Willis of Nottingham said that having read an account of the operation for cleft palate by the method of fracturing the upper maxillæ, he performed it, following most carefully all the details as described by Mr. Edmund Owen. His experience had been most unfortunate, the child getting necrosis, which was shortly followed by septic bronchopneumonia and death.

**A Case of Talma-Morrison Operation for Cirrhosis of the Liver.**—Mr. W. T. de C. Wheeler of Dublin reported this case. There was considerable ascites, the patient's general health was very bad, and he was much emaciated. The speaker opened the abdomen, withdrew the ascitic fluid, and brought the omentum up into the wound in the usual manner. The patient did extremely well, gaining 21 pounds in weight and regaining his health. It was suggested that the operation was Drummond and Morrison's, not Talma's, but Talma was the first to suggest its performance and Morrison himself recognized this.

**Ligature of the Innominate Artery for Aneurysm.**—Mr. W. Sheen reported this case, showing photographs of the patient. There had been symptoms for six months preceding the operation. He tied the artery by the Ballance stay knot so as to occlude it, but not break the inner and middle coats; no ill result followed, but there was a little chattering and mental disturbance. Pulsation, however, returned. A second operation was attempted, but bleeding deep in the wound made it impossible to proceed. It was therefore decided to tie the second part of the subclavian artery, and this was ligatured in two places at the third operation. The aneurysm was quite cured; it was now 16 months since the first operation.

**Two Cases of Partial Sloughing of the Vermiform Appendix.**—Mr. J. D. Malcolm reported the cases. He considered that this form of sloughing might occur without any symptoms, as in senile gangrene or in the wall of an ovarian tumor; it was not a true inflammatory process and possibly accounted for some anomalous symptoms in appendix cases. In each of the two cases a part of the appendix wall had undergone necrosis but there was no sign of surrounding inflammation.

**Epigastric Invasion of the Abdomen in Surgery of the Breast.**—Mr. W. Sampson Handley of London exhibited a number of lantern slides showing how invasion of the abdominal viscera usually occurred in cases of mammary cancer (see page 381).

## Medical Items.

**Contribution to the Physiopathology of the Pancreas.**—Pende tells us that when animals have had the duct of Wirsung ligated, the glands of the intestine, gastric and salivary, the liver and spleen show no alteration which would lead one to think of a vicarious action on the part of these organs. The secretory activity of the pancreas is suspended after about one week. A portion of the pancreas remains unaffected after the ligation for a long time, namely the islands of Langerhans. After some time they begin to take on retrograde changes, and begin to disappear. At the end of ten months they may still be found, but are so altered that it is evident that they are undergoing destruction. As regards glycosuria, animals without any pancreas do not differ from normal animals.—*La Riforma Medica.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service during the week ending September 2, 1905:

| | | CASES | DEATHS |

### REMARKS ON THE DIAGNOSIS OF DISEASES OF THE NERVOUS SYSTEM.*

BY JOSEPH COLLINS, M.D.,

NEW YORK.

No problem in clinical medicine presents so uninviting a prospect to the general practitioner as that offered by diseases of the nervous system. "You see, I know nothing about nervous diseases!" or, "Nervous diseases are too much for me!" are the most frequent comments that I hear from physicians whom I encounter in my work as a teacher and as a specialist. There seems to be an inherent conviction that the nervous system manifests the phenomena of disease in some obscure and mysterious way, *i.e.* in a way not apparent from inspection nor deducible from what is thus apparent, and, therefore, that it is futile to try and comprehend and interpret these phenomena without special training. In just the same measure as this is true for all problems of internal medicine, it is true for neurology, and no further. To one who has been made familiar with the problems of internal medicine by a service of ten years in the wards of a large general hospital, the feeling of the general practitioner confronted with the phenomena of nervous disease is inexplicable. Naturally, there are individual examples of disease of the nervous system which do not portray themselves in a characteristic way, just as there are examples of diseases of the pancreas, of the intestines, and of other viscera which lead to death, without having caused symptoms from a consideration of which the disease can be determined during life.

I am not endeavoring to gainsay that the diagnosis of the nervous system does not call for and require clinical training. I contend merely that it requires no more study, experience, or training—call it what you may—than does the diagnosis of diseases of the abdominal organs. Nearly every physician who is entitled to practice considers that he is competent to interpret the phenomena of disease of the abdominal viscera and with reasonable assurance that his interpretation will be correct, even though he has had no special experience or training in this direction. He brings no self-assurance to the interpretation of the phenomena of diseases of the nervous system; and this is the remarkable state of affairs to which I specifically draw your attention, and which I hope to be able to convince you should not exist.

During the past twenty years the recognition of nervous diseases has been tremendously enhanced by the cooperation of the physiologist, the anatomist, and the clinician. The result is that to-day the utilization of their united labors by any practitioner who wishes to do so, is one of the easiest things in internal medicine. As a matter of fact, the recognition of many organic nervous diseases is reduced to a mere matter of observation. The only excuse for not correctly diagnosticating many of them is that careful and intelligent observation are neglected. Take, for instance, the disease commonly known as locomotor ataxia. Its recognition depends upon the absence of response of the pupils to light, absence of the tendon-jerks of the lower extremities, disorder of sensibility in areas corresponding to the relation of the sensory nerves to the segment of the spinal cord from which they spring (segmental hypotonia and anesthesia), and the diminution of tone (hypotonia) of the muscles. Unless two or more of these conditions are present, it matters not what symptoms exist, it is scarcely ever justifiable to make the diagnosis. On the other hand, when two or more of them can be elicited, there is but one disease, and that the twin brother of tabes, general paresis, that can be confounded with it. The distinction can readily be made between tabes and general paresis in the vast majority of instances by the occurrence of symptoms indicative of a disordered mind in the former, in the shape of depression, expansion, or loss of insight. Naturally, an experienced clinician may be led to make the diagnosis of incipient tabes from a consideration of subjective symptoms alone, such as pain, just as he may make the diagnosis of gastric ulcer from a similar symptom, but it is not incumbent upon him to do so nor is it usually safe. Now no special training is required to test the knee-jerks, to examine the pupils to see whether or not they contract when a ray of light is directed into them, to know whether or not the tone of the patient's muscles is diminished so that there is greater mobility of the joints such as the knee and hip-joints than there should be, or, to determine whether or not there are objective sensory disturbances. The occasion, however, demands that the patient, who seeks relief from pain which he or his neighbor calls rheumatism, from hesitancy in starting the urinary stream, which he is inclined to attribute to an ancient gonorrhea, from diplopia, which he believes is due to some disease or disorder of the eyes, or from any one or more of the various symptoms which usher in tabes and which he attributes to this or that condition, should be subjected to simple examination just as he is subjected to an examination by palpation, percussion, and auscultation, if he comes complaining of pain in the chest, cough, or emaciation. A patient consults a physician for the relief of chronic abdominal pain. Such pain may be due to spasm of the colon, it may be due to chronic appendicitis, to subacute or chronic cholecystitis of various origin, to catarrh of the caput coli, to malignant disease, it may be the expression of a general neurasthenic condition, or it may be caused by several other conditions. The physician attempts to determine which one of these it is due to by examination. He neither takes the patient's interpretation of it nor does he attempt to treat him until he has satisfied himself of certain physical conditions. A similar attitude assumed towards the patient who comes complaining of the early phenomena of tabes will result in a correct diagnosis in upwards of three-fourths of the

* The Annual Address to the Lehigh Valley Medical Society, June 22, 1905.

cases. More than that—it will result in the diagnosis being made at a period in the course of the disease when treatment stands a fair chance of either permanently arresting the diseased process, or of so shaping its course that the patient's career is not materially changed by the disease. These remarks are as applicable to many other diseases of the nervous system as they are to tabes. I have singled out locomotor ataxia because it is the disease above all others which is most often incorrectly diagnosticated, and because it is the organic disease of the nervous system that offers the best opportunities for arrest or cure. I have records of upwards of three hundred cases of tabes. In about two-thirds the statement is made that the patient had been under treatment for rheumatism, neuralgia, flat feet, nervous prostration, etc., often for a period extending over years, before the real nature of the disease was recognized.

There are a number of nervous diseases characterized principally by wasting of the muscles and consequent functional impairment of the latter which may amount to a paralysis. These diseases are due to lesion of the spinal cord, of the peripheral nerves under which we include the nerve plexus, and of the muscles themselves. Such maladies may present themselves in an acute or chronic fashion and there may be any gradation between the acute and the chronic. Under this heading is included anterior poliomyelitis, which, when occurring in children, is often spoken of as the essential paralysis of children, multiple neuritis, multiple myositis, and progressive muscular atrophy of spinal, bulbar, neural, and myopathic origin. These diseases constitute a group which oftentimes present many difficulties of diagnosis to the general practitioner. When they occur without complications they should, however, be readily recognized provided that a certain fundamental knowledge of the anatomy of the nervous system is brought to the bedside. No one has studied medicine within the past ten years without having had to learn that there is a functional unit of the nervous system to which the name neuron is given. For a time it was thought that the functional unit was likewise an anatomical unit, in other words, that the nervous system was merely an aggregation of these units or neurons. Although this has been satisfactorily disproven, the neuron is for all practical purposes an anatomical unit as well as a functional one. This neuron consists of a cell-body and its integral substance, of a nucleus and nucleolus, of prolongations going out from the sides of the cell-body which are called dendrites and which are concerned very largely with the nutrition of the cell, and of a conductive prolongation known as the axis-cylinder or neuraxon, which goes from the cell in some part of the central nervous system to the periphery, and which constitute nerve roots and the peripheral nerves, and its termination. The motor cell-bodies and their immediate possessions, *i.e.* the dendrites, the integral structural substance of the body of the cells, the nucleus and the nucleolus, make up, with their supporting stroma, the anterior gray matter of the spinal cord, and of the medulla oblongata, which is the bulb of the spinal cord. Now, when these cell-bodies are the seat of disease, be it acute, subacute, or chronic, the effects of which it produces are manifest in the terminations of their respective axis-cylinders, which are, of course, in the muscles at the periphery of the body, the result being an impairment of their anatomical and physiological or functional integrity. This impairment is exactly in proportion to the intensity and extent of the lesion, whether the lesion be in the cell-body of the spinal marrow or in the conglomeration of neuraxons constituting the plexus of nerves, cervical, brachial, lumbar and sacral, in the individual nerves themselves after they have separated themselves from the plexus, or, finally, in the actively contractile muscular substance of the muscle to which the axis-cylinder distributes itself in the motor end-plate. Such an amount of anatomical and physiological knowledge must be brought to the bedside of a patient suffering from diseases of the spinal cord and of the nerves. Take, for instance, in a case of anterior poliomyelitis, there are first the general phenomena of an acute infectious disease, then within a very short time there develop paralysis of one or all of the extremities, rapidly increasing muscular atrophy, and finally contracture of those muscles which are not involved. The somatic phenomena of the disease is the same as it is in any acute infection, the particular symptoms upon which the diagnosis can be based are the result of the lesion or destruction of the cell-bodies of the neurons which are situated in the anterior horns of the spinal cord. If the focus of disease be in the cervical region, the muscles supplied by axis-cylinders going from the cervical region will be the ones that are atrophic and paralyzed. If it be in the cell-bodies of the neurons situated in the lumbar region, the muscles of the thigh and leg will be involved. If the focus of disease is very extensive it may affect both of these enlargements of the spinal cord and the sacral and dorsal divisions of the cord as well, in which case the resulting paralytic manifestations are very extensive. The disease, however, is not only apt to confine itself at least to one or two segments of the spinal cord, but generally it confines itself to one-half of one or two segments, *i.e.* the lesion is very much more intense in one anterior horn than it is in another.

In the beginning of the disease it may seem that the functional disturbances of the muscles are much more extensive and widespread, but after the acute manifestations have had time to disappear many of the groups of muscles, perhaps even an entire extremity which seemed to be functionless, are completely restored. If one waits until this stage of the disease, the diagnosis is comparatively simple. Now the clinical phenomena which are the result of destruction of the parenchyma of the anterior horns, *i.e* the ganglion cells of the anterior horn, may be produced by lesion of any part of the neuraxons in their course from the anterior horn to their eventual termination in the actively contractile part of the muscle substance. In other words, such phenomena may accompany neuritis and myositis. If the inflammatory process underlying each of these be limited to a strictly confined area, such as one or two nerves or a corresponding number of muscles, there will be very little danger of confounding the resulting condition with poliomyelitis, because the paralytic manifestations of poliomyelitis are rarely if ever thus confined. The problem is to distinguish between the paralysis and atrophy produced by poliomyelitis, polyneuritis, and polymyositis, the three conditions, which produce, on casual examination, similar phenomena. This is not difficult if it be kept in mind that the distribution of the paralysis and the atrophy is very unlike in the majority of cases of these three diseases. In poliomyelitis the paralysis and atrophy are usually limited to the muscles supplied by a certain group or groups of cells in one of the enlargements of the spinal cord. In multiple neuritis and in multiple myositis also, the paralysis and atrophy are confined to one or more extremities, and are likely to involve all the muscles of such an extremity, no matter what relationship these muscles have to the segments of the spinal cord from which their nerve supply comes. For instance, in polio-

myelitis accompanied by paralysis of one leg—let us say—one of the commonest occurrences is to have a paralysis of the extensor muscles of the foot, while the flexor muscles of the foot are relatively spared. In other words, the inflammatory focus has sought out the cells in the anterior horn from which the neuraxons going to the extensor muscles have their origin and has destroyed them, whereas a multiple neuritis which would cause a corresponding paralysis and atrophy of the leg, would be most likely to involve all the nerves of the leg, flexor and extensor alike, because the agency from which the multiple neuritis arose was probably conveyed to the nerves through the vascular system, and affects one and all of the nerves in the extremity alike. In the differentiation of multiple neuritis and poliomyelitis we have the very important sign that in the former there is almost invariably profound sensory disturbances, both subjective and objective, while in the latter there are no sensory disturbances after the acute manifestations of the disease have subsided, *i.e.* after the inflammation in the spinal cord has ceased to exist as an acute process. Of course, there are cases of motor neuritis in which the etiological factor, whatever it is, has confined itself almost wholly to the motor nerves, and in these cases the sensory disturbances are not very prominent. But even in these, the most important sign, viz., sensitiveness of the nerves to pressure, is invariably present. Therefore, in a case which presents the objective symptoms of poliomyelitis and multiple neuritis, the distinction is to be made by the presence or absence of sensory symptoms, subjective and objective. Moreover, in poliomyelitis, if the lesion is in or below the dorsal cord, there are often symptoms of sphincteric involvement and of vasomotor manifestations which are rarely if ever a constant accompaniment of multiple neuritis. If the problem be to distinguish multiple myositis, we have, as the most important symptom distinguishing the latter, more or less irregular swelling of the muscles that are the seat of the disease, the characteristic sensation which they produce to the touch, the irregular distribution of the inflammation in different muscles, and the very important different reaction which they give to the faradic current. In multiple neuritis, for example, the iritability of the muscle and nerve to the faradic current is less in proportion to the intensity of the inflammation. If the inflammation is so complete that the nerve is put out of commission, then the faradic irritability is entirely lost. This is not the case in multiple myositis. The faradic irritability is never entirely lost while there is any uninvolved muscular fiber remaining in the muscle. Myositis, whether single or multiple, is a diagnosis that is not very frequently made, and this, in face of the fact that it is of very common occurrence, much more common, indeed, than either neuritis and poliomyelitis. Many of the cases diagnosticated as neuritis, are in reality, cases of inflammation in the muscle substance, *i.e.* in the connective tissue part of the muscle substance. Some of these cases are diagnosticated as an excess of uric acid, as muscular rheumatism, as pleurodynia, as tender spots, as stiffness of the spine, etc. The clinical delineation of myositis, particularly in its simplest forms, has yet to be generally recognized.

When the peripheral neuron, *i.e.* the neuron extending from the spinal cord and its bulb to the surface of the body, degenerates slowly, it causes as its most conspicuous symptom a progressive muscular atrophy. If the seat of the lesion is the spinal cord proper, we call it a spinal progressive muscular atrophy, if in the medulla oblongata, we call it a bulbar progressive muscular atrophy or bulbar paralysis. If it is in the peripheral nerves, we call it neural progressive muscular atrophy, and if it is in the muscle substance itself, we call it a dystrophy. Now each one of these parts of the neuron is undergoing slow dissolution to constitute a chronic disease, doing it in a more or less characteristic way, and it is upon the recognition of those characteristics that the correct diagnosis depends. A more or less progressive atrophy of the muscles is the most conspicuous objective symptom of all of them, and a more or less corresponding progressive paralysis or functional inadequacy of the muscle is the conspicuous subjective symptom. In the case of the spinal muscular atrophies, the lesion is a gradual destruction of the cytoplasm of the cell-body and its dendritic processes, and the distribution of the atrophy corresponds to the situation and number of the cells involved. For instance, if the lesion is in the cervical enlargement of the spinal cord, the muscles of the hand and the upper extremities will show atrophy, if the lesion is in the oblongata the muscles of the lips, tongue, and larynx will manifest the atrophy, and in a similar way, if the lesion is in the lumbar enlargement of the spinal cord, the atrophy will appear first in the lower extremities. The essential point to remember is that the disease process is the same in each instance. If this one fact is kept in mind it contributes very materially to simplifying the diagnosis of the progressive muscular atrophies. One does not need to learn a different pathological description or etiology or prognosis or plan of treatment for spinal progressive muscular atrophy and for bulbar paralysis, because they are really the same disease, the only difference being that the seat of the disease is in different parts of the spinal marrow. The phenomena which they produce, it has been said above, are similar to those produced when the lesion is in the nerve itself, and not very unlike those resulting from a lesion of the termination of the neuron in the muscular substance, and the problem, therefore, is to distinguish between the progressive muscular atrophies dependent upon these three conditions. Now, what has been said in regard to the distribution of the atrophy in poliomyelitis, as compared with the distribution of the atrophy in multiple neuritis, applies just as truthfully to the distribution of the atrophy in the diseases under discussion, and, therefore, need not be repeated, though it needs to be emphasized because it is one of the important features in the distinction between the two diseases. Another symptom that is of great aid in distinguishing the progressive muscular atrophy of spinal origin from that of neural origin (a symptom that cannot be deduced from a consideration of the anatomy or physiology of the nervous system, and one, therefore, that must be learned by clinical experience), is that in the former, *i. e.* in spinal progressive muscular atrophy, the fibrillary tremor of the decaying muscles is a constant and almost pathognomonic symptom, while in its true form it never occurs in progressive muscular atrophy of neural origin. The distinction between the two diseases is further contributed to by an examination with the faradic current. In spinal progressive muscular atrophy there is a reaction of degeneration only in proportion to the amount of atrophy in the muscles, while in neural progressive muscular atrophy there is, if the disease is of any considerable intensity, an almost complete absence of faradic irritability. These features taken in conjunction with the presence of splanchnic symptoms in many cases of spinal progressive muscular atrophy and their absence in cases of neural progressive muscular atrophy, suffice to make the diagnosis. To distinguish either or both of them from the dystrophies, *i.e.* the form of progressive muscu-

lar atrophy in which the lesion is primarily in the actively contractile muscle substance, the point at which the neuron terminates, is easy in the majority of instances. In the first place, the latter is usually a family disease: it occurs almost always before adult life, and one variety of it, the commonest, is preceded and accompanied by voluminous enlargement of the outline of the muscle causing a spurious hypertrophy. There is no fibrillary twitching of the muscles, and there is rarely, if ever, any true reaction to degeneration to the electrical currents. Of course, when it comes to a differentiation between the three types of primary dystrophies, *i.e.* the type which is characterized by a spurious hypertrophy, the type which appears during the juvenile period of life, and the type in which the atrophy begins in or involves simultaneously the face and shoulder girdle, the matter is very different, and it is questionable whether the practitioner should be expected to make a differentiation. But once the dystrophy is recognized as such, then a consideration of its particular features will, if compared to the clinical descriptions given of the various forms in any of the text-books, lead readily to the differentiation.

Occasionally we encounter a patient who in addition to the objective symptoms of progressive muscular atrophy of spinal origin, has the phenomenon of spasticity, *i.e.* has an entirely new element added to the clinical picture, and this feature tends to befuddle the practitioner. Now, if the latter's knowledge of the rudiments of physiology be focussed upon the problem, however, this obscuration will quickly disappear. Everyone knows that the muscles are in a more or less constant state of tonicity, and this tonicity, which can be enormously increased by voluntarily contracting the muscle, is conditioned by the existence of some form of energy traversing the motor pathways from the beginning of the neurons in the cortex to their termination in the muscles. Anything that irritates these motor pathways naturally increases the tonicity of the muscles, and this stimulation becoming constant constitutes spasticity. Now, the motor pathways in the spinal cord are situated in the lateral parts of the cord, and when there is a disease characterized by trophic lesion of muscles we use the word amyotrophic to describe it, and if there is added to it the phenomenon of sclerosis in the lateral parts of the spinal cord, we call the disease amyotrophic lateral sclerosis. Amyotrophic lateral sclerosis has a very definite clinical course, quite unlike that of spinal progressive muscular atrophy. This alone is amply sufficient, even though there were no other reason, for calling it an entirely different disease, but it is not to that point that I wish particularly to draw your attention, but rather to the ease with which the disease is diagnosticated. Unless one himself has seen and watched a case of the disease, or unless he has recognized it and has had the course of the disease impressed upon his mind by reading about it, he naturally cannot have a knowledge of its clinical display, which makes it an entirely different disease from spinal progressive muscular atrophy. Progressive muscular atrophy plus spasticity of the extremities with its invariable coexisting phenomena, *i.e.* increase of tendon jerks, exalted direct myotatic irritability, the Babinski toe-phenomenon, *i.e.* simultaneous extension of the big toe and flexion of the small toes when the plantar surface of the foot is stroked with some rough object, such as the end of a match, are quite enough upon which to place the diagnosis.

In this connection I wish to say a word concerning the diagnostic significance of the Babinski toe phenomenon. Although there is a vast amount of literature on the subject, considering that it is scarcely seven years since Babinski called attention to its occurrence, I am inclined to believe that popular dissemination of it is still wanting, considering that it is as Babinski maintained, a sure means of differentiating certain organic lesions of the central nervous system from functional lesions which simulate them. For instance, it is oftentimes very difficult to say whether hemiplegia is hysterical or organic. The occurrence of the Babinski toe phenomenon makes it absolutely certain that it is not hysterical. In the same way it is often of the greatest importance in differentiating hysteria from disseminated sclerosis. As a matter of fact it may be stated positively that it never occurs in an individual above one year of age, who has not an organic nervous disease which implicates the upper motor neurons, *i.e.* the neurons extending from the cortex of the brain to their distribution around the ganglionic cells of the anterior horns of the spinal cord and oblongata. In infants up to one year of age, *i.e.* before the primary motor neurons are clothed with their normal myeline sheaths, the Babinski jerk is a natural possession. I make this statement knowing that occasionally there is a Babinski phenomenon after an epileptic convulsion, and occasionally in strychnin poisoning and in tetanus, but to these exceptions no attention need be given. The test is so simple and gives such important and valuable information that it should be made a part of the routine examination in all cases in which there are any symptoms of nervous disease.

Progressive muscular atrophy of spinal, neural, and muscular origin causes a complex of symptoms which is wholly motor. There are rarely any sensory disturbances, even the slightest. There is a disease of the spinal cord, however, which causes muscular atrophies plus distinct disturbances of sensibility. This disease is called syringomyelia, a compound word meaning a channel within the spinal cord. Syringomyelia is a disease that should be diagnosticated with very considerable readiness, because its recognition is almost entirely dependent upon the presence of muscular atrophy in one or more members of the body plus a peculiar disturbance of sensibility. This peculiarity of sensory disturbance consists in a relative preservation of tactile sensibility with blunting of pain and thermal sensibility. There are naturally many other objective symptoms that occur in syringomyelia dependent upon the seat and extent of the cavity formation within the center of the spinal cord. It is only within the past ten or twenty years that this disease has received the recognition that it merits. Even to-day the diagnosis does not seem to be made with anything like the same frequency here as it is abroad. For instance, in Strümpell's clinic in Erlangen, the statistics show that it is the third most common organic disease, disseminated sclerosis and tabes having precedence of it. In my own clinic for ambulatory cases only, it has been diagnosticated but 15 times during the past 7 years, during which time about 7,000 cases of nervous disease have been examined. In the same time 142 cases of tabes and 22 cases of disseminated sclerosis have been seen. It is a disease, however, that is often overlooked and there is very little doubt, I think, that the majority of the cases are classified as progressive muscular atrophy.

There is no disease in the entire domain of neurology that is so often incorrectly diagnosticated as the one known as multiple or disseminated insular sclerosis. In Great Britain and in all European countries it is one of the commonest organic nervous diseases, while in this country it is one of the rarest. This state of affairs is almost inexplicable on any other ground save the lack of recognition of

the disease on our part. It cannot be that the same race, existing under practically similar conditions in different countries, reacts differently to the cause of diseases. As a matter of fact, the diagnosis is probably never made in this country except, perhaps, by a few neurologists in any case in which the so-called cardinal symptoms—intention tremor, scanning speech, and nystagmus—are not present, and as these so-called cardinal symptoms are not present in the majority of the cases of disseminated sclerosis, it will readily be seen why the disease seems to be so rare in this country. I do not mean to be understood as saying that the apparent infrequency of the disease in this country is to be explained wholly by our failure to diagnosticate it. That accounts for the situation only in part, because when one is most alert to recognize it and is ready to include under the caption cases that are only suspected to be multiple sclerosis, even then the disease is relatively uncommon. All that can be said to the general practitioner concerning the diagnosis of disseminated sclerosis in patients who do not present the so-called cardinal symptoms, is that whenever an individual under 35 years of age, free from syphilitic infection, who has developed symptoms of any or all of the extremities without sensory disturbances, is encountered, the suspicion should be raised that he is dealing with a case of dessiminated insular sclerosis. If there should be added to this disturbance of vision which can be shown to be dependent upon atrophy of the optic nerves indicated by progressive pallor in the temporal portions of the discs, hurried action of the sphincters amounting at times to incontinence, or an ataxic tremor of any of the extremities, disturbances of articulation, ataxia of coordination, and especially if there are remissions in the course of the disease during which time the patient would seem to be getting well, the practitioner may be almost certain that he is dealing with a case of disseminated sclerosis. It is readily appreciated, considering the fact that the islets of sclerosis may be situated in any part of the central nervous system, that the symptoms which may result may parallel those of almost any organic nervous disease. For instance, if the patches of sclerosis affect principally the posterior columns of the spinal cord, the symptoms of tabes may make up the clinical picture. On the other hand, if they are situated in the anterior or anterio-lateral part of the spinal cord, the clinical picture may be that of amyotrophic lateral sclerosis or of lateral sclerosis alone. As a matter of fact probably more than two-thirds of the cases diagnosticated as lateral sclerosis are cases of disseminated insular sclerosis. On the other hand, if the islets of sclerosis are scattered more or less across the spinal cord, the clinical picture will be that formerly described as chronic myelitis and there is no doubt, I think, that nearly all of the cases formerly diagnosticated as chronic myelitis which were not the sequelæ of acute myelitis and other infectious disease, were cases of disseminated sclerosis. In the same way it is easy to understand that the disease may produce very bizarre symptoms, symptoms that do not conform in their grouping and other mode of display with any known organic disease. Likewise, it may be readily understood that the lesion of disseminated sclerosis may be so distributed that it will produce in the same individual and at the same time mental, emotional, and physical symptoms which cannot be interpreted as due to involvement of any definite part of the central nervous system. The recognition of this fact permits us to understand why it is so difficult at times to distinguish between disseminated sclerosis and hysteria which, by the way, is one of the most difficult distinctions the physician has to make. On an occasion such as this I can hint only at the necessity for making this distinction without entering into the details of both diseases. I venture to say, however, that within the coming decade disseminated sclerosis of the central nervous system will be very much better understood in this country than it is to-day.

To turn now to that form of progressive muscular atrophy which is dependent upon a lesion of the collection of cells or motor nuclei, from which spring the motor nerves going to the lips, tongue, and larynx, and which is commonly called glossolabiolaryngeal paralysis. As I have said before, the disease process and the clinical features of the disease are exactly similar to those of spinal progressive muscular atrophy, *i.e.* objectively they are made up of atrophy of the muscles, and subjectively, loss of function of these muscles. Anyone who will give the time to a consideration of what the symptoms should be in such a case, can easily portray them for himself, even though he has never seen a case of bulbar paralysis. Despite this, it is remarkable the number of cases of the disease that one sees that have never been diagnosticated. There are two conditions from which, however, this disease is not diagnosticated very readily; one is an inflammation of the peripheral motor nerves which have their origin in the medulla, bulbar neuritis as it is sometimes called, and the other is the disease known as asthenic bulbar paralysis. The history of a preceding infectious disease, the absence of fibrillary tremor, the absence of any symptoms of spasticity, and the comparatively slight atrophy might always tend to suggest the former. Asthenic bulbar paralysis is the name given to a complex of symptoms similar to those produced by gradual destruction of the motor nuclei in the oblongata constituting glossolabiolaryngeal paralysis, which symptoms often lead to a fatal termination, the most careful macroscopical examination of the nervous system, central and peripheral, failing to reveal any lesions to which the symptoms can be attributed. The disease is, therefore, sometimes known as bulbar paralysis without anatomical foundation. The first case of this sort to be recorded in this country was one published by myself in the *International Gazette* in 1894. The disease was first described by Wilkes in 1877 and by Erb in 1878, and popularized by Oppenheim of Berlin in 1887. Since then, a large number of genuine cases have been recorded. In lieu of giving a description of the disease, I shall read you the notes of a recent case.

The patient was a young woman 21 years of age, who noticed first when she was 19 years old, that her speech took on a nasal twang. Even previous to this time, however, she had remarked that she became exhausted after talking for any length of time, and that on such occasions her speech would become indistinct. The next symptom to develop was attacks of choking and coughing caused by the passage of particles of food into the larynx. The next symptom was occasional regurgitation of liquid through the nose. These three symptoms developed within six months from the time that she began to ail. A physician who treated her at this time said she had paralysis of the palate. She was constantly under treatment for nasal catarrh. She got gradually worse and people noticed that her speech became very thick and that her eyes were not right, especially that they did not close completely. About this time she began to complain of difficulty in opening her fingers especially when they were flexed. She had to struggle hard to get them open. She became very easily exhausted on comparatively slight efforts of walking and talking, and she noticed that

when she attempted to do any work it caused tremor or trembling of her hands. When she first came under my observation, on January 8, 1903, she complained of weakness of the deep muscles of the back, of diplopia, which she said was of about two months' duration, of numbness and jerky movements of her arms, especially when reclining, of heaviness of her head, of vertigo, of palpitation, insomnia, leg-weariness, occasional balooning of the abdomen, indistinctness of speech, difficulty in swallowing, attacks of spasmodic coughing and choking, a constant desire to expectorate, and of unwieldiness of the lips, face and tongue.

Examination showed a well-developed young woman of pasty complexion, mucous membranes rather pale, lines of the face obliterated, partial ptosis of both eyes, inability to obliterate the palpebral fissure on attempts to close the eyes, slight paralysis of the internal recti muscles of the right eye which caused a divergent squint. The facies of the disease is well shown by the accompanying illustration from a photograph (Fig. 1). Her facial appearance when she attempted to open her eyes wide is shown in Fig. 2. Vision of the right eye 20/20, left 20/40. Inability to pucker the lips. The tongue could not be protruded beyond the teeth and on continued effort in this direction was accompanied by irritation of the throat and desire to cough. During phonation the palate remained almost immobile, but the uvula was drawn to the right side, and the pharyngeal reflex was markedly diminished. There was no atrophy of the tongue or lips or of the face, and no fibrillary tremor. The reflexes of the upper extremities were about normal and the motor power of the hands and arms was diminished. The knee jerks were normal. The skin was dermographic. The sensibility all over was intact. The special senses were not impaired. The blood examination showed hemoglobin, 65 per cent.; erythrocytes, 5,505,000; color index, 0.6; leucocytes, 11,300. The differential count showed polymorphonuclear, 64 per cent.; lymphocytes, 22 per cent.; eosinophiles, 1 per cent. The blood stained well. There was considerable difference in size and shape of the cells with rather a prevalence of large cells. Polychromatophilia slight. There were no nucleated red cells, and no plasmodia seen. In other words, the type of the blood was that of a person suffering from a moderate chlorosis with a relative increase of the mononuclear elements.

In the upper extremities the peculiar reaction of nerves and muscles known as the myasthenic reaction, was easily elicited. This reaction, which was described by Jolly, consists of a normal response of the nerves and muscles where the faradic current is first applied, which response, however, rapidly exhausts. The neuromuscular apparatus regains its irritability after a short rest. The patient's symptoms fluctuated in intensity, being very much increased by everything that caused fatigue. She died in a state of exhaustion from dyspnea, the phenomena of bulbar paralysis having been intense for several days before her death.

Much experimentation with drugs was made upon her, the hypodermic administration of bichlorid of mercury, the administration of parathyroids, thyroids, etc., not having had the slightest effect upon her. An autopsy could not be obtained.

Asthenic bulbar paralysis, or myasthenia gravis, as it is often called, is a condition that the practitioner should have in mind when he meets a patient under thirty years of age, who presents symptoms of ptosis, inability to close tightly the eyelids, easily induced fatigue of the facial muscles or any of the ordinary symptoms of bulbar paralysis.

The diagnosis of intracranial diseases oftentimes presents the greatest difficulties with which we have to contend. The commonest intracranial lesion producing the phenomena is disease of the blood vessels, disease which eventually leads either to thrombosis or to rupture constituting apoplexy.

Fig. 1.—Facies in myasthenia gravia.

Fig. 2.—Myasthenia gravia; facial expression when attempt is made to open the left eye.

Much has been written concerning the means of differentiation of the three commonest causes of cerebral apoplexy, *i.e.* of embolism, thrombosis and rupture, but despite this it is frequently a very difficult differentiation to make, as a large number of autopsies in the City Hospital have convinced me. Nor can it always be made with anything like satisfaction from a history of the case and a consideration of the clinical phenomena of the disease. The foreshadowing symptoms of cerebral apoplexy are very much the same whether the apoplexy be dependent upon a thrombosis of the blood vessels or upon rupture of them, and in many cases there are no symptoms whatsoever, previous to the occurrence of the attack. It must be admitted, however, that these cases constitute the exception and that the symptomatology of cerebral arteriosclerosis and cerebral endarteritis has yet to be adequately written. We are told that vertigo, headache, forgetfulness, insomnia, a feeling of apprehension, are the most conspicuous symptoms of cerebral arteriosclerosis. It is probable that they occur when the sclerosis is most developed in the basilar artery and its immediate branches; but when

the process is rather generalized these symptoms do not, by any means, constitute the clinical picture.

As a matter of fact, the symptoms of neurasthenia, somatic, mental or splanchnic, occurring in an individual who has physical evidences of arterial degeneration manifested by increased blood pressure as determined by any of the various blood-pressure apparatuses, thickening of the walls of the blood vessels determined by palpation, and especialy if associated with tachycardia or bradycardia, a deficiency in the elimination of solids manifest by a continued low specific gravity of the urine, oftentimes the existence of granular casts, mild cardiac hypertrophy and well-marked accentuation of the second sound are in reality the symptoms of arterial sclerosis and should lead to the diagnosis of this condition in the vast majority of instances.

The most desirable equipment for the diagnosis of cerebral apoplexy is an intimacy with Bright's disease. The term Bright's disease is, in the mind of nine-tenths of us, synonymous with a primary disease of the kidney, such as acute exfoliative nephritis. In reality this is not Bright's disease at all as the term is now being employed. It would be desirable to drop the term Bright's disease altogether, but as this is impossible, we must teach our successors to use it only to designate a systemic disease caused by the presence of toxins of different origin in the circulation. It is complicated now and then with kidney disease, but it is by no means a necessary acompaniment, and the kidneys are probably not oftener involved (not nearly so often in my own experience) than the brain.

It is not my purpose to dwell here upon the etiology or most probable pathogenesis of this systemic disease. In the first place it is not germane to the subject, and in the second place I have it under consideration in another connection. It is my desire, however, to emphasize the fact that if arterial fibrosis in all its phases was recognized, many diseases, both mental and nervous, would lose their obscurity.

I shall probably succeed better in conveying to you the manner in which arterial sclerosis often presents itself to the neurologist, by citing a few cases rather than by discussing the subject academically. For instance, let us take the case of a lady 57 years old, who, when she was 50, had an attack very similar to that for which she consulted me, and another when 56. When she came to see me in February, 1904, she said she was troubled with her head, but it seemed as if there was some power or perhaps voices that permitted her to say or do things which she did not want to, and which she was convinced was not proper for her to do. The constant struggle against the dominion of this power or voices had exhausted her. She suffered a great deal from insomnia, from loss of physical energy, and her peace of mind was much disturbed. A year before coming to see me she had had a similar attack, but that lasted only two or three months. In the summer of 1893 she had had occasional attacks of vertigo and considerable daily headache, but she did not attach much importance to these symptoms. Her present symptoms began rather suddenly in January, 1904. She was sitting at the table at noon time and experienced a sensation as though some one had struck her on the head. She knew that this was the beginning of her "nerves" as she calls them.

Her complaint was that she tired easily, that she had no peace of mind. She is not quite sure that what disturbs her are voices, but she is constantly being prompted to do something contrary to her wishes. If she decides to go to church, to go shopping or to come to see me, something like a voice impels and argues and threatens with her in order to keep her from going. To use her own language: "All the time I am trying to fight it off, but they seem to make me give in and I get very little peace. They tell me about ordinary things that I should do and say. For instance, this morning on my way here, they argued with me and tried to convince me that I should not come. It is a terrible thing, and I can't stand it any longer!" She is not constantly depressed, but she often cries, particularly after these voices have been very troublesome. She has a great deal of difficulty in sleeping, sometimes difficulty in going to sleep, and oftentimes great difficulty in staying asleep. She complains of a feeling of weight on the top of her head, of an empty sensation in the head, of loss of ambition, of lack of interest in her family, and in things that previously absorbed her. Her weight is about ten pounds under normal, and there was a history of considerable polyuria.

Examination revealed a blood pressure of 160 with the Stanton apparatus, small, rather feeble pulse, thickened blood vessels,, accentuated second sound. The urine showed a specific gravity of 1,008, 2,000 cc. per diem, hyaline and a few granular casts. The diagnosis of arterial sclerosis was made and the patient put under the appropriate régime and medical treatment which she continued for some months with considerable benefit. Her family were apprised of the condition and the danger of apoplexy, but as soon as she improved in her most distressing symptoms, treatment ceased. About a year after I saw her I received a letter from her husband in which he said that the patient had a short time previously suffered a stroke of apoplexy. There were no symptoms previous to the attack. She appeared to be as well as usual when she came down to breakfast. Her daughter, who was breakfasting with her, went out for a few minutes and upon her return found her mother stooping over trying to lift the morning paper from the floor, which had fallen out of her hands. She did not loose consciousness, but her speech was indistinct for about an hour. The right arm was partially paralyzed, and the right leg almost wholly paralyzed. Many such cases could be cited if anything were to be gained.

In some instances the attack of apoplexy comes on abruptly and without any warning symptoms whatsoever even though the arteriosclerosis upon which the rupture of the vessel is dependent is most extensive and has renal complications. In illustration of this, I cite briefly the following case: A male negro, 46 years old, was brought into the hospital in an unconscious state. His wife stated that she had never heard him complain of illness, and that he worked steadily. He had gone out after supper to do an errand, was stricken in the street and soon became unconscious. Examination showed that the urine was heavy with albumin, that it contained granular and hyaline casts, that the heart was enlarged upward of a half inch beyond the nipple line, its action irregular, and that a double murmur was to be heard over the aortic area. The left half of the body was partly paralyzed. Blood pressure with the Riva Rocci apparatus was 185. The following day the patient was still unconscious, the left hemiplegia complete and he had incontinence of urine. The next day, in addition to these symptoms, he had the phenomena of collapse, the blood pressure fell, and the following day he died.

The autopsy showed in addition to the extensive generalized arterial sclerosis with the ordinary secondary changes in the heart, an extensive hemorrhage into the right lateral ventricle, which was the cause of the coma, hemiplegia, and death. The ac-

companying illustration, Fig. 3, shows the right lateral ventricle, the floor of which is lacerated from the hemorrhage which involved the corpus striatum and the optic thalamus.

The reason why it is so necessary to make the differential diagnosis between apoplexy produced by thrombosis and that produced by rupture of a blood vessel is that the appropriate treatment for the one is very much unlike that for the other. I know of nothing that will contribute more to a correct differential diagnosis than the use of the blood-pressure apparatus. This is an instrument which should be in quite as constant use as the stethoscope, and the clinical thermometer. It is inexpensive, portable, and requires no experience in order to use it effectively, and the result of its measurements can be relied upon. Notwithstanding our experience, all of us are often in error concerning the existence of increased blood pressure when we rely for its detection upon the sense of touch alone. Of course, I do not mean to say that the early diagnosis of cerebral arterial sclerosis and cerebral endarteritis hinges upon the readings of the blood-pressure apparatus, what I do mean to say is that the recognition of this

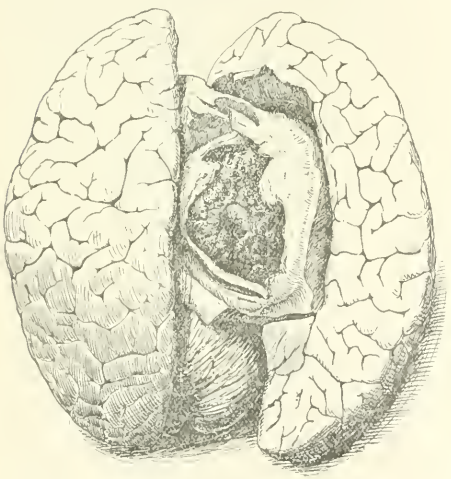

Fig. 3.—Hemorrhage into the lateral ventricle; viewed from above.

disease is tremendously facilitated by its intelligent use. When the attack comes that these diseases herald, then the differential diagnosis is difficult enough to permit us to reach out for any aid at hand. Amongst these the blood-pressure apparatus is one. When the apoplexy is dependent upon the rupture of a blood vessel, the blood pressure almost invariably falls, and this fall in the arterial pressure keeps up for a variable period from a few hours to one or two days, after which the blood pressure gradually increases until it measures, let us say, 200 on the Stanton apparatus, or 250 on the Riva-Rocci, until it reaches the degree that existed previous to the rupture of the blood vessel. On the other hand, in apoplexy due to cerebral thrombosis, the blood pressure does not fall during the apoplectic attack or soon after; it may, however, be fairly low for some days after the attack, and continue low for an indefinite period.

The most difficult task in my teaching in a graduate medical school, is to convince those to whom I demonstrate the diseases of the nervous system and the morbid pathology upon which they are dependent, that there is such a disease as acute parenchymatous inflammation of the cerebrum similar to acute tonsilitis, acute pneumonitis, acute pancreatitis, acute orchitis, or any other acute inflammation of a viscus, to which the name acute encephalitis is given. Particularly difficult do I find it to portray in a convincing manner to them that there is such a disease as acute nonsuppurative encephalitis, which is often confined to comparatively narrow parts of the cerebrum and especially of its cortex. From my intercourse with such graduates I venture to say that the diagnosis of acute nonsuppurative localized encephalitis is rarely or never made by the general practitioner. Still, it is not a very uncommon disease. It is much more common than sporadic meningitis for which it is often taken. If we exclude from the category of meningitis all the cases due to the intracellular diplococcus, the tubercle bacillus, and the toxin of syphilis, there will be very few cases of meningitis left. As a matter of fact, the cases that are considered to be meningitis, are, many of them, cases of encephalitis. For instance, I will cite the most recent case of encephalitis which I have seen. The mother states that when her child was 13 months old, and had already accomplished considerable in the way of walking and talking, it suddenly became ill, was nauseated, vomited, irritable, and restless. When the doctor came he said the child had a high fever. That night the child had general convulsions and after this was stuporous and unconscious for about two weeks, when it gradually regained consciousness, but went into a condition which the mother characterizes as one of being limp all over. Gradually it grew better, but as it grew stronger it was noticed that there was a slight paralysis on the right side of the body. The child was brought to the clinic because of an occasional epileptic fit which he has now at the age of 11 years, the first of these having shown itself when he was 7 years old.

It would not seem difficult to interpret the sequence of events as they developed in this child by assuming an acute infectious inflammation within the cranial cavity which rapidly confined itself to a limited space in the motor area of which the initial convulsions were the expression. The disturbances of the intracranial circulation, not only in the areas where the inflammatory exudation was, but throughout the entire intracranial contents caused the prolonged coma or unconsciousness, while the protracted prostration and general flaccidity resulted from an interruption of the transmission of sensory impulses to and motor impulses from the cortex. Finally, the slight hemiplegia and occasional epileptic attack, depended upon the destruction of certain neurons in the cortex of the hemisphere and upon the sclerosis or scar tissue, the sequela of the inflammation. Even though there had been such symptoms of meningitis present as stiffness of the neck or opisthotonus, transient strabismus, projectile vomiting, wiry pulse, and other phenomena which are put down in the books as very significant, the fact that the symptoms mentioned before existed, would still suggest and justify the diagnosis of encephalitis. The fact of the matter is that the diagnosis of meningitis is often to be made from a consideration of the clinical symptoms, but when there is any doubt about the diagnosis, the practitioner should call to his aid the information to be obtained from a lumbar puncture. There should be no more hesitancy about making a lumbar puncture than there is about putting a small exploratory needle into the pleural cavity, and probably no one hesitates to confirm or deny the suspicion of pleural exudate by thrusting a small needle between the ribs. Lumbar puncture has come to be an almost routine method of investigation in my hospital practice, and

I have never seen any untoward results from it. Before leaving the subject of meningitis, I wish to say a word about the most important objective symptom, Kernig's sign, the essential of which is a contracture of the flexor muscles of the lower extremity, especially the thigh, and which shows itself best when an attempt is made to straighten the leg at the knee on a semiflexed thigh. It is now more than twenty years since Kernig first called attention to this phenomenon, and stated that it was pathognomonic of meningitis. Perhaps it is because of our great familiarity with the various forms of meningitis due to its commoner occurrence that Kernig's sign has only recently had the attention it deserves, although it is not pathognomonic of meningitis, since it has been shown to be present in such disease conditions as sciatica, cerebral or cerebellar hemorrhage, hysteria, and in certain toxic conditions that simulate meningitis (meningismus) it has real diagnostic importance and occurring in conjunction with other symptoms of meningitis it tends to make certain the diagnosis.

The diagnosis of suppurative encephalitis, *i.e.* of brain abscess because almost invariably the suppurative inflammation is circumscribed, is a very difficult matter and in the majority of cases it can only be surmised, or based upon the existence of a previous suppurative inflammation of the middle ear and perhaps of mastoid involvement as well. It is the one intracranial disease which at the present time offers a sufficient inviting field for the surgeon to make him in any way enthusiastic about intracranial surgery, but unfortunately, the difficulties surrounding satisfactory localization of the brain abscess are so great that but few of them are successfully operated upon unless the abscess is situated in the motor region of the brain or unless it confines itself somewhat narrowly to the first temporal lobe of the left side. The reason for this is readily understood when we consider how remote and far-reaching the effects of a suppurative inflammation within any viscus may be, *i.e.* how easily it is for these sypmtoms to obscure those symptoms which are said to be pathognomonic of the disease itself. I have recently had a case in my hospital practice that illustrates the truth of this statement abundantly. A widow, 37 years of age, came into the hospital complaining of pain in the head and in the left side of the face. Three months before coming into the hospital she had an abscess on the right side of the face, *i.e.* an alveolar abscess involving the antrum. She had some teeth drawn at that time and the abscess was treated in another hospital. Before that she had had the headache of which she now complains. She does not remember just when they began. She says that a year before she used to have fainting spells and had pain in different parts of her body and felt stiff in the chest. In addition to the pain in her head and face she complained of vertigo, of occasional vomiting, of hot spells every few minutes in the head and the upper part of the trunk, and of exquisite tenderness on the top of her head, especially the right side. Aside from a tender spot in this location and tender spots on deep pressure in different parts of her body, there were absolutely no physical signs. The optic discs were normal, there was no paralysis or impairment of motility, no alteration of the tendon jerks, in fact, there was not a single objective sign. The temperature was normal, pulse 72, blood pressure 120. She grew steadily worse from day to day, complaining bitterly of pain in the left side of face and head, and moaning and groaning constantly. After about a week, a small puffy tumor was detected over the seat of tenderness on the scalp. A needle thrust into this revealed the presence of pus. It was then laid open and a search made for its origin without finding it however. The autopsy made one week later revealed a focus of suppurative periostitis, a small area of suppurative pachymeningitis, but no evidence of disease of the brain.

The fundaments of cerebral localization are essential to every practitioner. A knowledge of them can easily be acquired in ten minutes. If one learns to draw the relative positions which the fissure of Sylvius and the fissure of Rolando have in the hemispheres, he has no difficulty in acquiring the essential facts of cerebral localization. These facts are not only of the greatest importance in assisting in a satisfactory diagnosis of cases of brain tumor and abscess, but they permit of a satisfying interpretation of the ordinary case of aphasia. In order to put before you convincingly the results of the simple application of the rudiments of localization, I cannot do better than by quoting the following case:

A young man twenty-five years old came to the clinic to seek relief from epileptic attacks which he had had during the past two years. His history was that he had had syphilis when he was twenty one, for which he received some treatment, and he married when he was twenty-four. In addition to the attacks of epilepsy, which I shall describe in a moment, he complained that his head felt light and dizzy most of the time. He made no complain of headache but occasionally he said there was a pain over the left eye, nor was there any history of vomiting, disturbance of vision, or locomotion. His wife's description of the attacks which he has is as follows: "His eyes get large and wild looking, he jerks his shoulders and lifts his left hand up toward his heart, then he shakes like all over, but the left one shakes most when he is coming out of the attack. He is unconscious for about half an hour, sometimes longer. He drools, but he does not froth at the mouth. When he comes out of an attack he goes into a doze. At night when he is asleep he is always twitching and he often awakens and asks if he has had an attack. The first one he had was in his sleep. Sometimes I find his pillow wet in the morning even though he has not had an attack so far as I know." His own account of the attacks is that he suddenly, without warning, is conscious of a vile smell and this lasts for from one to ten minutes. Then suddenly everything gets dark around him and he loses consciousness; he never has an attack in his waking moments without the olfactory aura that I have just mentioned. The fact that the hippocampus and uncinate gyrus is the center for the sense of smell, that the young man had syphilis, and the fact that he had none of the somatic features of epilepsy, led me to diagnosticate a gumma of the uncinate gyrus and to urge him to go into a hospital for treatment. I urged this particularly upon him as an ophthalmoscopic examination showed beginning choked discs on both sides. To-day he is completely restored to health. He has no attacks of any sort nor has he had for upward of five months, and all his symptoms have disappeared. The treatment administered was large doses of bichloride of mercury hypodermically, and a drachm of iodide of potassium three times a day.

A working knowledge of the facts of brain localization consists in the recognition of the fact (1) that the motor area of the hemispheres is situated just in front of the fissure of Rolando, and extends from the top to the bottom of that fissure. The part of the motor area that is in front of the top of the fissure, presides over the movements of the trunk and leg; that in front of the middle one-third of the fissure presides over the upper extremity, viz., the shoulder,

elbow, wrist, and fingers, named in the order of their allotment from above downward, while to the part in front of the lower one-third of the fissure is alloted the centers for the face and its various components. Now, if a patient has an attack of convulsions in which the initial spasm or twitchings are confined to a definite part of the body, let us say the fingers, a knowledge of the fact that the area for the fingers is situated just in front of the fissure of Rolando at the junction of its middle lower third, will lead us to seek for the lesion at this spot and in the hemisphere on the opposite side of the body to which the convulsions are manifest. The nature of such a lesion, whether it is a tumor, abscess, fecal sclerosis, vascular lesion, etc., must be inferred from the history of the disease and from the general symptoms.

(2) The next most important point to remember about cortical localization, is that the part of the brain which interprets sensory perceptions is that immediately behind the fissure of Rolando. (It should be said here that many neurologists believe that the central convolution behind the fissure of Rolando also participates in the motor allotment, but the trend of opinion seems to be toward limiting the motor allotment to the ascending frontal convolution.) The limitations of sensory localization to the cortex of the brain have never been adequately worked out and the practitioner can expect but little information concerning the location of any lesion in the brain from a consideration of the sensory symptoms alone, unless it be from that sensory symptom which is known as astereognosis. Astereognosis or loss of the capacity to recognize objects from the various sensations which the object produces when it is placed in the hand, may be an important symptom of cerebral disease pointing to involvement of the parietal convolution just behind the fissure of Rolando. (3) It must needs be a matter of common knowledge that a large part of the surface of the brain is taken up with the allotment of centers which preside over the faculty of speech. At one time it was thought that the speech area was a small center situated at the base of the third frontal convolution, oftentimes spoken of as Broca's area because of the French physician who first called attention to the relationship between diseases of this area and disturbances of speech. For a long time, however, it has been well known that the speech centers occupy a large area on the lateral surface of the brain, and that in right handed individuals it is made up of the base of the left third frontal convolution, almost the entire first temporal convolution, and a very considerable part of the inferior parietal convolution; and that in left handed persons a similar area exists on the right side of the brain. In this area there are three distinct centers. The center for articulate memories, which is situated in the third frontal convolution, the center for auditory memories in the first temporal convolution, and the center for visual memories in the angular gyrus or posterior end of the inferior parietal region. It naturally follows that a person who has lost the memory of the articulation of words has a lesion at the foot of the third frontal convolution; one who is word deaf, has a lesion in the superior temporal convolution and one who is word blind, has a lesion in the angular gyrus. In addition to this it must be kept in mind that the posterior poles of the brain, the cunei, as the wedge-shaped ends of the occipital lobes are called, are the eyes of the cerebrum. They act as the mirrors to which the retina sends images, each cunei being the cerebral mirror, as it were, for a half of each eye. When a cuneus is therefore the seat of disease, there will be blindness of one half of each eye, and this blindness is called homonymous hemianopsia. If, in any given patient with symptoms of cerebral disease any of these gross objective symptoms are elicited, a comparatively small familiarity with the facts of cerebral localization will readily lead to the localization of the disease. It is not at all necessary to have a comprehensive understanding of the complex anatomical arrangement of the different components of the central nervous system. It is not necessary even to have a profound knowledge of the physiology of the brain in order to satisfactorily localize the commoner lesions of the cortex. When the disease affects the interior of the brain, or when it involves the basal ganglia and the numerous small but all-important structures at the base of the brain, then the topical diagnosis is oftentimes difficult and occasionally impossible.

In conclusion I wish to say that the diagnosis of nervous diseases is almost wholly dependent upon observation and interpretation. Some nervous diseases can be diagnosticated from a consideration of the patient's statements alone, but the physician who relies upon such data in order to make a diagnosis must very often err, no matter how great his experience or how profound his clinical acumen. If patients who suffer from nervous diseases are subjected to well-known methods of examination and the results of such examinations recorded and then thought given to their interpretation, particularly in the light of the time and way in which they occurred, there are scarcely any of the ordinary organic or functional diseases of the nervous system that will not readily be recognized. As was said in the beginning of this paper, the reason why nervous diseases are considered to be a strange country by the general practitioner, is (1) because there is an inherited conviction that such diseases are extremely obscure; (2) because there is an acquired conviction that in order to unravel the intricacies of such diseases, a comprehensive knowledge of the anatomy and physiology of the nervous system is required; and finally, because many physicians do not take the trouble to acquaint themselves with the simple methods of testing for the existence of nervous disease. Any medical man who will put himself outside of these three limitations or obsessions, will have no more difficulty in dealing satisfactorily with nervous diseases than he has with any other disease in the province of internal medicine.

37 West Fifty fourth Street.

## A CASE OF LARYNGEAL DIPHTHERIA, NECESSITATING INTUBATION, COMPLICATING CEREBROSPINAL MENINGITIS IN AN ADULT.*

By W. K. SIMPSON, M.D.

NEW YORK.

PROFESSOR OF LARYNGOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY.

The object of reporting the following case is to demonstrate that cerebrospinal meningitis and true diphtheria may consist in the same patient and that the respective bacilli are not necessarily antagonistic one to the other. The importance of recognizing the fact of this coexistence comes with great force at the present time, since during the recent epidemic of cerebrospinal meningitis in and about New York the assertion gained some credence that the two diseases could not occur together, and—based upon this assumption—the treatment of cerebrospinal meningitis by injections of antidiphtheritic serum

* Read at the twenty-seventh annual meeting of the American Laryngological Association, June, 1905.

was extensively indulged in, with the hope that a true specific might be at hand. Unfortunately, the results of the treatment were such that at present it has been practically abandoned, with a consensus of opinion that it had no appreciable effect on the course of the disease.

Seemingly this should prove that the two diseases are separate entities, but a stronger proof is afforded, I think, when we can find the two diseases actually existing at the same time, as was stated in the outset of this paper, and which the history will sustain.

The patient was a married woman, aged twenty-seven years, first seen by me in consultation January 10, of this present year. She had been ill for twenty-two days, beginning with symptoms which finally terminated in a well-marked case of cerebrospinal meningitis, having all the classical phenomena, namely, eruption (which occurred December 30), hemorrhagic in certain areas, stiffness of neck, prostration, restlessness, photophobia, delirium, Kernig's sign, exaggerated reflexes, small feeble pulse, irregular and elevated temperature, and facies typical of meningeal involvement.

On January 9, the day previous to my first seeing her, and while she was still in the midst of her cerebrospinal symptoms, she complained of hoarseness, some croupy cough, and beginning laryngeal dyspnea. These symptoms steadily continued to increase, so that at the time of my first examination, January 10, they were pretty well advanced. On examining the larynx at this time I found the entire lumen filled with a distinct thick membrane, markedly impeding respiration, and peculiarly limited above by the arytenoid cartilages, there being no membrane at this time, or subsequently, in the pharynx.

The membrane had all the characteristics of being diphtheritic in nature, and I attempted to take a laryngeal culture, but owing to the increased dyspnea which the effort produced I was only partially successful and the culture proved to be negative. The laryngeal dyspnea continued in severity to that extent that within a few hours after my examination intubation became necessary. This was successfully performed and gave marked relief to the difficult breathing.

The following day and again subsequently large pieces of membrane were expelled through the tube, from which pure cultures of the Klebs-Loeffler bacilli were procured—thus confirming beyond question the diagnosis of laryngeal diphtheria. The tube was removed at the end of the fifth day, and during the time it was *in situ* there was complete relief from the dyspnea. Examination of the larynx after extubation showed some redness and swelling about the superior portions of the larynx. Hoarseness, cough, and some spasmodic breathing occurred during some days following extubation, but at no time was it considered at all necessary to reintubate, nor was there any subsequent appearance of membrane.

Immediately after the first laryngeal examination —January 10—antitoxin was administered by injection and was continued until January 19, 30,000 units being given within that period.

Inasmuch as this case occurred at the time when the treatment of cerebrospinal meningitis by the injection of antidiphtheria serum was being advanced, the effect of the administration of the serum on the cerebrospinal symptoms was most carefully watched and recorded, and without going into detail, which is not within the scope of this article, I may say that the opinion of those immediately in attendance was that there was no appreciable effect produced on the course of the cerebrospinal meningitis. On the contrary, it was during the administration of the serum, and also after it was stopped, that lumbar puncture was performed, in all, three times—January 13, 22, and 26, there being drawn off respectively two ounces, one ounce, and ten drachms. In each instance was found the characteristic meningococcus intracellularis. It is possible to suppose that if diphtheritic antitoxin was in any way antagonistic to cerebrospinal meningitis its administraton would show ts effects in the destruction of these characteristic cocci.

There were times after the onset of the diphtheria and during the administration of the antitoxin when some of the cerebrospinal symptoms seemed to modify, especially in the occasional mental clearness and stiffness of the neck, but these changes, together with marked irregularity of heart action, were no more than occur in uncomplicated cases of cerebrospinal meningitis. The subsequent progress of the case was marked by the continuance of irregularity of heart action, irregular and high temperature, and the development of pneumonia, death occurring on January 26, apparently of heart failure, being thirty-eight days from the beginning of her illness and seventeen days after the onset of the diphtheria.

No autopsy was held.

The importance of making a laryngeal examination in this case, and in all acute cerebral diseases, at the onset of laryngeal symptoms cannot be too strongly emphasized, for had not an examination been made in this instance at the very outset, the patient would surely have succumbed to acute laryngeal obstruction, and the death might have been attributed to pressure symptoms due to extension of the cerebral lesion. That the degree of the diphtheritic involvement was extensive is shown in the production of such marked stenosis, for we know that it is comparatively rare for diphtheria in the adult to produce sufficient laryngeal obstruction to require operative interference.

It was not my intention in the recital of this case to enter at all into its minute detailed history, but only to record the coexistence of the two diseases with such other data as would naturally be considered. A most complete bedside history is on file, which may be consulted.

I wish to acknowledge the kindness of Dr. John S. Thacher of New York, to whom I am indebted for being called in consultation, and through whose courtesy I am permitted to make this report; also to Dr. A. J. Brown of the Presbyterian Hospital, for his assistance in preparing the notes.

## GALL-BLADDER SURGERY.*

By T. C. KENNEDY, M.D.,

SHELBYVILLE, IND.

This is certainly the age of surgery, and in calling your attention to the rapid advances that have been made in the surgery of the upper abdominal zone, I want to express the hope that we may not see the pendulum swing to that extreme that a few years ago was the case in appendicitis and diseases of the ovaries. The rage for doing appendectomies and ovariotomies went too far, and it is now feared by many that cholecystectomies and cholecystotomies may also be overdone. In many cases of disease of the gall-bladder we must resort to operative procedure, but we must be diligent in our search for those cases that will yield to internal medication and treat them rationally with complete relief to the patient. It has been advocated by some surgeons when doing an abdominal section that the appendix should always be removed, whether diseased or not, and before long

* Read before the Surgical Section of the Indiana State Medical Society, West Baden, Ind., June 8, 1905.

some enthusiast will advise us always to do a cholecystectomy when operating in that region. The first thing of importance is to get a complete history of the case, as the diagnosis must largely depend upon our knowledge of the number of attacks, the kind of pain, and the condition of the stomach and pancreas. A careful examination should be made of all the other organs, as we must differentiate between cholecystitis and appendicitis, renal colic, duodenal or gastric ulcer, and pancreatitis. Very frequently it is impossible to make a diagnosis of the exact condition, but we are called upon to decide whether it is a case that will yield to medicinal treatment or is one that can be cured only by an operation. An exploratory incision will reveal the character of the operation necessary, and the operator must be prepared to do a cholecystectomy or cholecystostomy if the indications call for it. Many cases of gall-bladder disease have been loosely diagnosed as gastritis, indigestion, dyspepsia, gastric catarrh, or neuralgia of the stomach, and after being treated by one physician and getting no relief from the suffering, the patient drifts to another physician, who calls the trouble by another name, but treats it with the same result. We must look to the general practitioner for a diagnosis in these cases, as the patients always go to him first, and if a careful study of the case is not then made, the true seat of the disease may be overlooked. A great many of these patients are permitted to drift along, and will only consent to an operation when they regard it as the last chance, and when they reach the operating table they are many times in an almost hopeless condition, and then have to endergo a much more severe operation than would have been necessary in an earlier stage of the disease. Kehr says: "The slight danger of an early operation stands in no sort of relation with the great danger of the disease itself."

Another thing the surgeon frequently has to contend with in these old, long-standing cases, is the morphine habit. These patients invariably do badly, and are the source of great concern; they have extreme nausea, take insufficient nourishment, have obstinate constipation, and oftentimes collapse suddenly. It is my invariable rule to refuse operation on a patient whom I know to be a confirmed user of morphine. In obtaining the history of these patients, it may be impossible to ascertain the true condition of affairs. While admitting that they take the drug to relieve the seizures of pain, they deny strenuously that they ever take it between the attacks. I want to impress upon the minds of the general practitioner the great importance of informing the surgeon of this habit if it exists. The mild cases of inflammation of the gall bladder are very difficult to differentiate; these are the cases that are diagnosed as stomach trouble, especially when there is vomiting, after which the patient feels better; then we have the cases that simulate appendicitis so closely that they may be mistaken for that disease, and still further to add to the confusion, we may find both diseases existing at the same time, as I did in a case which was referred to me recently. Ochsner and La Place have reported cases in which they found suppuration coexisting in the appendix and gall-bladder. In many cases it is difficult to differentiate between a cholecystitis and cholelithiasis, and Rolleston goes so far as to say that the distinction is an artificial one; while Mayo Robson contends that cholecystitis or chronic catarrh of the gall-bladder without jaundice forms a separate, distinct, and definite disease.

It is not my desire, however, to deal with the symptomatology or pathology of gall-bladder diseases, but to take up more particularly a few important points in the operative procedure. It is impossible to tell in any case what operation may be necessary, but fortunately for both the operator and patient a simple cholecystostomy is all that is necessary in the greater number of cases; however, it may be necessary to do a cholecystectomy or a choleystenterostomy, and the operator must be prepared for every emergency. I have adopted the incision of Bevan, the lower end of the vertical incision being carried outward and the upper end upwards and inwards. I have never found that the long incision complicates recovery, or tends to hernia, if proper care is taken in stitching the wound. The incision should be long enough to enable the operator to make a careful examination of the gall-bladder and the bile tract. I generally make an incision about three inches long and extend it as much as is deemed necessary. I saw Kehr operate upon one case in which the incision seemed to be at least ten inches long. I have never had a postoperative hernia in these gall-bladder cases. A fistula will not result if there is no occlusion of the ducts and we are careful to stitch the gall-bladder to the aponeurosis. The most important thing in gall-bladder surgery is thorough drainage; I believe better results will be obtained in all cases that are drained, and I now invariably keep up the drainage until the inflammatory process subsides. The operation of shoice is cholecystostomy; the tendency is more and more toward cholecystectomy in all cases, but I think this should be practised only when there are positive indications. Deaver says: "I believe the gall-bladder is an essential part of the hepatic apparatus, otherwise nature would not have made it, and being a great respecter of nature, I am very slow to oppose her; while on the other hand, I do believe that the cure obtained by the judicious application of the aseptic scalpel of the surgeon in many cases excels nature's cure. I entertain the same view in connection with the appendix, as that recently exploited by Sir William Macewen, who has given his opinion that the appendix has a valuable function as a part of the digestive apparatus. I have always thought it unwise, yes, I may say meddlesome, on the part of surgeons to remove the appendix in performing an abdominal operation for some other trouble simply because the appendix was so accessible, and I entertain the same view in connection with the gall-bladder."

It is now generally conceded that cholelithiasis is a surgical disease and the stones cannot be dissolved by medicines, although Richardson says: "It is evident, then, that by administering sodium glycocholate, it must be possible not only to prevent the formation of gallstones, but also to dissolve those that have formed." Brockbank says that "not one new remedy of any great value has been discovered in the past one hundred and fifty years." I want to give a short report of a few cases here:

Case I.—I was called to see Mrs. S. about midnight of August 26, 1904. She is 64 years old, the mother of eight children. I obtained the following history: In 1899 she had a severe attack of typhoid fever and was confined to her bed eleven weeks. In May, 1900, she was seized with severe pain in the stomach, which lasted for about one-half hour; the pain was followed by vomiting; these attacks occurred during that year three or four times; one attack was accompanied by a slight jaundice; the appetite was always bad for several days after these attacks. The attending physician pronounced it neuralgia of the stomach, and gave a hypodermic of morphine to relieve the suffering. She had these attacks at intervals of a few weeks; once she went for four months without an attack; when she congratulated herself that she was cured. At the time of my visit she was suffering excruciating pain in her

stomach and back; she had a temperature of 101°; the entire upper abdominal zone was tender on pressure, but the greatest tenderness was found over the gall-bladder. A diagnosis of gallstones was made, which she did not accept readily, as her case had always been pronounced neuralgia of the stomach. She refused operative procedure, which was advised, and I resorted to all the known remedies, such as olive oil, phosphate of sodium, salicylic acid, etc. After a trial of three months she finally consented to an operation, which was performed November 10, 1904. Upon making an incision through the upper rectus muscle, I found the gall-bladder somewhat contracted and greatly inflamed; upon incising the gall-bladder I removed 102 stones. No stones were found in the duct. A drainage tube was placed in the gall-bladder; the gall-bladder was stitched to the aponeurosis, and the abdominal wound was closed by through and through sutures. As my assistant remarked, she never had enough symptoms after the operation to make it interesting, and she made an uninterrupted recovery: the appetite has been good; the stools of normal color and no constipation; there has never been any return of the symptoms.

Case II.—Mrs. Y., age 32, mother of two children, had a severe attack of catarrhal jaundice about five years ago; since that time she has suffered a constant pain in the right hypochondrium opposite the ninth rib; she complained of a dragging sensation in the side with intense burning. Had indigestion, coated tongue, and constipation, losing strength and weight gradually. She was brought to my hospital February 2, 1905. I made the usual Bevan incision; there were adhesions with the stomach and duodenum which were separated. The gall-bladder was inflamed and thickened. I opened the gall-bladder, which contained about one-half ounce of thick, glairy fluid; a drainage tube was placed in the gall-bladder which remained eleven days. She remained in the hospital four weeks, at the end of which time she was discharged, and has had no returns of the symptoms; she has steadily gained in strength and weight.

Case III.—Mrs. C. of Marietta, Ind., aged 64 years, was referred to me by Dr. Walter C. McFadden. She has been suffering with a pain in right side for two years, but no distinct history of gallstone attacks; about one month prior to my first visit she became jaundiced and at the time she was suffering with cholemia; the itching was intense night and day, and she could get no relief; the stools were of a grayish color, there was entire loss of appetite, and she could get no sleep; she was taken to my hospital and operated upon April 1, 1905. The gall-bladder was distended, and from it I removed fourteen and one-half ounces of fluid. I also removed a stone about the size of a quail's egg from the cystic duct; it was not necessary to open the duct, as the stone had barely entered the mouth of the duct, and I was able to work it back into the gall-bladder. The head of the pancreas was slightly enlarged. At the time of operation, owing to her condition, it was deemed unwise to do an anastomosis of the gall-bladder and duodenum. A drainage tube was placed in the gall-bladder and the latter stitched to the aponeurosis. About the third day the jaundice began to disappear gradually, and with it the pruritus; appetite improved and strength returned; on the twelfth day she sat up for about one hour. At this time, about two months after the operation, the drainage continues; the head of the pancreas is constantly enlarging, and we have a well-marked case of cancer of the pancreas. Mayo Robson says that "all cases of distended gall-bladder accompanied by jaundice are not due to obstruction of common duct by stone, but is due to cancer of the pancreas or the common duct."

Case IV.—Since writing this paper, I operated upon Miss L. of Vincennes, Ind., who was referred to me by Dr. S. C. Beard. She was 35 years old; her mother died of cancer of the stomach; she had a severe attack of pain in July, 1901, which was referred to the stomach and radiated to the left side; she has repeated attacks which occur with increasing frequency, the attacks being followed by intense vomiting and retching; there is some pain under right shoulder blade. I operated upon her on June 3. Upon making an exploratory incision, I found evidence of gastroduodenitis; there were dense adhesions which were broken up with difficulty; the gall-bladder was inflamed; the pancreas was somewhat thickened; cholecystostomy was performed and the drainage is still in; she has done well since the operation; but what the result will be in this case, it is too early to determine.

On August 3 I received a letter from this patient's father, now two months after the operation, saying that she has not had any of her old "sick spells" since she came home, and is getting along nicely.

---

## THE INFLUENCE OF PNEUMOCOCCI ON THE HEALING OF WOUNDS, WITH THE REPORTS OF A FEW CASES.

By J. WIRT ROBINSON, M.D.,

BOZEMAN, MONTANA.

The great difference in the appearance of wounds is constantly noticed by medical men. Wounds which are "clean" are a most pleasant sight, while those which are infected, especially if they are suppurating, are an eyesore to the surgeon. There is a great difference even in the appearance of suppurating wounds. This was noticed by the ancients, who used to speak of "pus laudabile et bonum," and "pus malignum."

There are a number of reasons for variations in appearance. Clinically, the better known causes are divided into: (1) The variations in the kind, number, or virulence of the infecting bacteria. (2) The variations in the resistance of the body. The variations in the resistance of the body are divided into general and local. General factors are: (1) The age of the patient; (2) the general condition, nourishment, amount of hemoglobin, etc.; (3) presence or absence of constitutional diseases, chronic poisoning, etc. Local factors are: (1) The tissue infected; (2) the amount of blood supply; (3) presence or absence of traumatism; (4) the treatment the wound has received. Scientifically, the differences are well explained by the beautiful side-chain theory of Ehrlich.

If sutures be present in a wound which is suppurating, great irritation and severe reaction usually occur. Redness and induration develops, then pus formation and more or less cutting of the sutures follow. In colon bacillus infection the irritation and cutting of sutures seem to be the worst. Next are those by staphylococci and those by streptococci. Naturally, however, there is a variation in the order; but in my experience infections due to pneumococci have been quite different. The following cases will illustrate this:

Mrs. T., German, married, and twenty years old, gave this history: One year ago she reached full term of pregnancy, and labor pains set in. A physician was called to attend her. However, he was unable to deliver the child, and, after several attempts with forceps, decided to have a consultation. The consultant discovered a tumor in the pelvis, which blocked the passage of the child's head. Owing to the poor condition of the mother and of the child,

cesarean section was not advisable; so an opening was made in the posterior cul-de-sac, and the tumor removed in sections. It proved to be a dermoid cyst. After removing the cyst the child was extracted, but did not live. The puerperium was not one free from worry, but in time the patient was able to get around again. She did not feel well, however, and later the symptoms became so severe that she applied for treatment. The diagnosis of a pelvic abscess was made. An exploratory laparotomy was performed. Before as many sponges as were necessary had been placed to protect the general peritoneal cavity, the abscess was accidentally ruptured, and pus flooded the peritoneum and edges of the incision. A rubber drainage tube was pushed through an opening in the posterior cul-de-sac. The peritoneum was cleaned as well as possible, and the abdominal wound closed. The next day evidences of peritonitis, extreme tenderness, meteorism, rapid, thready pulse, and facies hippocratica developed, and conditions did not look very hopeful for recovery; but after two more days these symptoms were almost entirely absent, and from then on she went on to good recovery. In spite of the fact that the abdominal incision was contaminated with pus, it healed by primary union. There was no redness nor induration around the sutures. Examination of the pus showed the pneumococcus in pure culture.

The following is another case of pneumococcus infection of the peritoneum: A. S., American, age twenty-four, had had several attacks of severe pains in the right iliac region, with fever and vomiting. During the last attacks he submitted to an operation. A large abscess was found and opened. The appendix appeared in the field of operation, and was removed. The incision was partially closed, but free drainage was secured. The course was favorable for two days; then pain developed in the right hypochondriac region, and slight jaundice appeared. Thirty-six hours later he had a chill; the temperature rose to one hundred and three degrees, the pulse to one hundred and sixty, and was very weak, and the respirations were as high as sixty per minute. Examination showed dullness over most of the lower left lobe of the lungs, the lower part of the upper left lobe, and areas scattered through the right side. This critical condition remained for five days, when improvement gradually occurred. The lungs were very slow in compensating for the infarcts, and several months later examination would reveal the lesions. From the first the abdominal wound did well; the discharge was not excessive and gradually grew less. The part of the wound that was sutured together healed by primary union; there was an absence of the red, angry look and induration so often present. In six weeks the patient was walking around a little. Examination of the pus showed a pure culture of the pneumococcus. It was fortunate that the infection was with a pure culture of this special organism, because I do not believe he would have recovered under any other conditions.

Mrs. M., Italian, aged thirty-three, and married, complained of pain in the left lumbar region. Previous history pointed somewhat to renal calculi, but the symptoms had not been present for two years. Examination showed a slight rise in temperature, pyuria, and tenderness of the left kidney. After the usual preparation, an incision was made and the kidney exposed. Upon opening the kidney a few drachms of pus flowed out. No calculi were found. The incisions were partially closed, leaving free drainage. Urotropin was given internally. The discharge of pus and urine was quite free for a few days, and then rapidly decreased; the pyuria also disappeared rapidly. In two weeks the discharge had entirely ceased. The part of the incision that was sutured healed by first intention, and even where the drainage tube was, little scar tissue formed. The pus contained a pure culture of pneumococcus. How different this case was from some other cases of pyelitis in which other bacteria were present.

In several cases of empyema due to the pneumococcus alone, and in which other infection was avoided, healing of the skin incision was rapid, and with little inflammatory reaction. Of course, where the tubes were, healing could not occur.

From these cases, although few in number, we may draw the following conclusions:

1. The pneumococci, if alone, cause little inflammatory reaction in the healing of wounds.

2. Possibly, in surgical diseases caused by pneumococci, some protective substance is formed that ameliorates the symptoms, as occurs in the crisis of a pneumonia.

3. In the treatment of a pus case care should be used to prevent a mixed infection, as healing is much more apt to be rapid and smooth if only one variety of bacteria is present.

## REPORT ON THE CONTROL OF TUBERCULOSIS IN THE PHILIPPINES.*

By D. M. APPEL, M.D.,

LIEUT. COLONEL, DEPUTY SURGEON-GENERAL, U. S. ARMY.

One would imagine that a paper on "The Control of Tuberculosis" read before a medical audience in the Philippines would of necessity treat largely of causes of the disease peculiar to the tropics, under the impression that the disease is there more widespread and that this is due to the existence of such causes.

The fact is, however, that though the disease ordinarily makes more rapid progress here, especially in transients, it is, generally speaking, more prevalent in colder climates. It is estimated that among the more civilized communities under improved social conditions the death rate from tuberculosis is still over 13 per cent. of the total mortality.

In Manila, which is certainly the most populous and congested part of these islands, about 10 per cent. of the total deaths among residents is due to tuberculosis, whereas among transients, those not included in the census returns as a part of the permanent population) 12 per cent. of the total mortality is due to this disease. This disparity is readily accounted for and is in reality greater than is shown by the statistics, as quite a few of the latter class return to their homes to die. A large majority of the transients are young male adults, so that we to a great extent eliminate the diseases of childhood in computing the percentages of death. Furthermore, as but comparatively few Americans and north Europeans are suitable for tropical climates, they become more susceptible to tuberculous infection from the debility so frequently resulting from the enervating effects of acclimation.

Most of the transients, on the other hand, are in good physical condition on their arrival, and the percentage of deaths from this disease, notwithstanding the increase from elimination of children's diseases and from climatic influences, is lower than is general in civilized communities.

Therefore, the conditions we have to contend with in controlling the disease in these islands do not differ materially from those existing elsewhere. Here, as everywhere the important influences on the spread of the disease are overcrowding, poverty, poor and insufficient food, and general neglect of children.

* A paper read at the second annual meeting of the Philippine Medical Association.

The most important factor in colder countries, overcrowding with resulting defective ventilation, is to a considerable extent eliminated here, especially among the poorer natives, for, excepting in a very few densely populated localities in this city, ventilation cannot be prevented in their napa shacks.

Tuberculosis is preeminently due to lessened tissue resistance and the predisposing causes are consequently more important than in any other infective disease. While without bacilli there is no tuberculosis, I as firmly believe that one in normal physical condition is not susceptible to infection under ordinary conditions.

Improved general hygienic conditions are therefore equally as important as the destruction of the bacilli-containing sputa in the control of the disease.

In the last published report of the Commissioner of Public Health, which is for the year ended September 1, 1903, the following remarks of Major Carter are universally applicable to the lower classes even in the most civilized communities. He says that "undoubtedly the greatest obstacle to improving the native is the native himself"; and again, "whatever has been done has only been accomplished by constant endeavor and the exercise of much tact in the face of general opposition on the part of the natives who are naturally slow to change the habits, customs, and ideas inherited from their forefathers, and who, being strongly imbued with superstitious beliefs and fatalistic ideas, cannot understand the utility of carrying out the proposed reforms."

Our efforts, therefore, for the suppression of the disease must be directed towards educating the public. We should teach it not only the source and nature of the infection and the ways in which it can be conveyed, but also the means to be employed to assure its destruction. It is, however, advisable in this connection, while insisting on the danger of infection, at the same time to make it clearly understood that the disease is not contagious, and thereby prevent the panicky dread of association with the affected so apt to become prevalent in communities living in localities to which the tuberculous resort.

The disease is not contagious, nor is any one in good health susceptible to infection. Only when the tissue resistance is lowered either locally or generally does the bacillus get in its deadly work, for we find surgical tuberculosis usually affecting parts that have been subjected to slight trauma reducing the resistance of the parts without destroying their vitality.

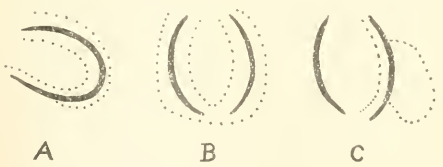
For an effectual campaign against tuberculosis it is necessary to adopt some system of notification and registration of all cases, to enable the health authorities properly to supervise them, to give detailed instructions in their management and in the measures to be employed for the prevention of infecting those in attendance, especially insisting upon the destruction of the bacilli in the sputa. Such cases as cannot be properly cared for in their homes should be segregated either in sanatoria or colonies, because the proper treatment of pulmonary tuberculosis involves not only great hardship for the patient but requires infinite care and patience on the part of the attendants.

## THE AORTIC REFLEXES.

By ALBERT ABRAMS A.M. M.D.,
SAN FRANCISCO, CAL.

THE writer has elsewhere (*American Medicine*, April 2, 1904) briefly referred to the aortic reflexes. Their importance in medical diagnosis is, in the opinion of the writer, so great, that he wishes once more to exploit their clinical value. To elicit the reflexes in question, I now employ no instrumental aid, contenting myself with the use of my hands after the following method: The palm of one hand is applied closely and firmly to the spinous processes to be concussed, while the other clenched hand is employed as a plexor, striking the dorsum of the first hand a series of sharp, vigorous blows. To elicit the aortic reflex of dilatation, one concusses after the manner cited, the spinous processes of the eighth, ninth, tenth, eleventh, and twelfth dorsal vertebræ. Immediately thereafter (for the reflex is of short duration—from one-half to one minute) percuss with a strong blow the region of the thoracic aorta, and the course of that vessel, even in the norm, may be defined. The course of the upper surface of the normal aorta in the adult of middle life may be projected on the chest by drawing a curved line, beginning at a point corresponding to the right sternal line in the middle of the first intercostal space, and ending at the point of insertion of the first rib to the sternum. The highest point of the aortic arch is distant about 5 cm., and the beginning 2 cm. from the anterior thoracic wall, hence a forcible percussion blow which is propagated to a depth of about 5 cm. cannot fail to elicit the dullness of the aortic arch if it is dilated. In the elicitation of the reflex in question, one must be chiefly guided by the sense of percussional resistance. Concussion of the spine of the seventh cervical vertebra after the same manner causes the aortic dullness to evanesce at once, as a result of the counter reflex of aortic contraction.

That alternate dilatation and contraction of the aorta follow the concussional maneuvers already mentioned, may be shown by the Röntgen rays. Many control investigations have demonstrated that the lung (lung reflexes of Abrams) is in no wise implicated in the percussion changes. The Röntgen rays pictures employed for control purposes fail to correspond in degree with the decided changes noted by percussion. The latter fact is in accord with reason, considering that, while percussion produces results varying with the approximation of the aorta to the thoracic wall, with the rays the sagittal diameter of the aorta is not taken into consideration. The same fact is pertinent in determining the relative shadow of an aneurysm by the *x*-rays and the area of dullness by percussion. More than two years experience with the aortic reflexes shows them to be fairly constant, but variable in duration. In an



accompanying illustration, A shows the areas of a thoracic aneurysm in a patient seen in consultation with Dr. J. B. Frankenheimer of this city. The aortic reflexes were specially pronounced, and this, despite the fact that theory would have dictated otherwise, considering the supposititious annihilation of the vessel's elasticity. The continuous line of A, represents the area of percussional dullness of the aneurysm, whereas the dotted lines within and without the continuous line represent respectively the reflexes of aortic contraction and dilatation. In B, practically the same results are noted in a case recently seen in consultation with Dr. A. J. Sanderson of this city. This case was specially interesting for the reason that we could control our concussional

results by means of the *x*-rays. C represents such results observing the patient with his back approximating the fluoroscope. The continuous line represents the shadow outline of the aneurysm, whereas the dotted lines within and without this line represent respectively the reflexes of aortic contraction and dilatation. Note that although B and C represent the same aneurysm the percussion results in B in no wise correspond with the skiascopic results in C, and for the reasons already adduced.

At my suggestion Dr. Sanderson will employ vibration treatment directed to the seventh cervical vertebra, for it is not unreasonable to assume that if concussion will secure contraction of the aneurysmal sac to the degree shown in the illustration (which is a reduced reproduction), the same maneuver may, if repeated often enough, be of remedial value.

*Postscript.*—It may prove interesting to note the results achieved by vibration applied to the seventh cervical vertebra in this patient. On July 7, 1905, treatment was commenced. The patient at this date complained of violent pains in the chest and dyspnea on the slightest exertion. On August 2, 1905, the *x*-ray shadow of aneurysm was denser, and the aortic reflexes could not be elicited. I attribute the latter to clot formation in the aneurysmal sac, which inhibited whatever elasticity remained in the aortic walls. At this date aneurysmal pulsation, formerly present, could no longer be seen with the rays. Percussion no longer yielded any dullness over the site where it was present. Tracheal tugging was barely perceptible. The thoracic pains had disappeared, and there was no longer any dyspnea on exertion. On September 1, 1905, Dr. Sanderson informs me that the only symptom which remained at the time of the discharge of the patient was slight tracheal tugging, and a letter received from the patient indicates that he is able to resume work and continues to feel perfectly well.

## ON THE ROLE OF TRICHOCEPHALUS IN THE ETIOLOGY OF TYPHOID FEVER.

By GIUSEPPE SPEZIA, M D.,

TURIN, ITALY.

At a meeting of the Académie de Médecine de Paris, held October 18, 1904, Professor Blanchard read a communication on this subject, presented by Dr. Gujart. In twelve cases of typhoid fever this observer had detected in the feces an average of two eggs of trichocephalus for each microscopical preparation. On the other hand, in the feces of persons affected with other diseases, there was none or only one in a great number of preparations. Dr. Gujart thinks that the intestinal parasite is an indirect cause of typhoid fever, for in attaching itself deeply to the intestinal mucosa by its tapering anterior extremity, it makes a wound through which the bacteria enter, causing the infection. The bacillus of Eberth is none the less specific.

I have made similar observations in nineteen cases of typhoid fever during the course of the present year. In the nineteen cases examined I found the eggs of trichocephalus in the feces in seventeen, an average of three eggs being noted in each microscopical preparation. Four preparations were made in each case, and the average number of eggs in each case was twelve. The presence of the eggs seemed to have no special relation to the day of the disease or to the physical character of the feces.

In other diseases, especially of the gastrointestinal tract, the eggs of trichocephalus are rarely seen. I found only one or two in a number of preparations. The only exception was in two cases of ankylostomiasis, in which there were a great number of eggs of trichocephalus in addition to the ankylostomata. In some cases of typhoid fever there were a great number of eggs of ascaris lumbricoides, to which perhaps one may attribute a rôle similar to that of trichocephalus.

In view of the results of my own observations I am led to agree with Dr. Gujart regarding the importance of the trichocephalus in typhoid fever. Among the many writers who have proved that wounds of the intestinal mucosa may be inflicted by trichocephalus, I would mention Wrisberg, Luckardt, Boas, and Askanazy. One might hazard the conjecture that the more abundant development of trichocephalus in the intestine is only a consequence, and not a predisposing cause, of typhoid infection, but I think this is disproved by the well-known fact that the period of development of the trichocephalus from the egg in the stomach (Davaine, Bouchard) to its adult stage covers a month and more; whereas, I have found the eggs of the parasite in typhoid stools in the first few days of the disease.

I think also that, given the enormous quantity of eggs of trichocephalus in the dejecta of typhoid patients, it is necessary to use disinfectants which will not only destroy the bacillus of Eberth, but which are able also to dissolve the resistant covering of the eggs of the trichocephalus (as for instance concentrated solutions of potassium or sodium salts) in order to prevent further infection of healthy persons with the eggs, these being known to develop directly in the stomach of the man without an intermediary host.

---

**A Case of Curious Cardiac Action.**—Theodore Fisher recounts a case in which there were very unusual movements of the heart that could be both felt and seen. The patient had been treated for cardiac disease for a year and a half. Three weeks before admission she began to feel a peculiar double impulse, which was present at the time of examination. There was slight precordial bulging; the impulse was best in the fifth interspace, three and three-quarter inches to the left of the sternum. There were two distinct beats, the first being most marked at the apex, the second nearer the sternum. Over the whole heart area there was a reduplicated first sound, the interval between the two sounds being distinct. Over the second and third interspaces there was a reduplicated second sound. There was a widely distributed systolic murmur, and a diastolic rumbling heard at the base. The heart was beating slowly, 44 to 52 per minute. There was a visible pulsation in the right external jugular vein, occurring before the carotid pulse. After rest in bed the double impulse disappeared and there were the signs of a mitral regurgitation. Pulsation in the internal jugular may be due either to contraction of the right auricle or of the right ventricle. If the ventricles acted independently, and the impulse near the sternum was systolic contraction of the right ventricle, the pulsation in the veins would be synchronous with the impulse near the sternum, as in this case. —*Medical Chronicle.*

**Febris Enterica Sine Febre.**—Sir Dyce Duckworth reports this case. The patient was a boy sixteen and a half years old who was admitted to the hospital on January 9. The boy had vomited and had abdominal pain the day before admission; later he had headache and was drowsy. The temperature on admission was 102.4°. The spleen was enlarged and tender, and there was no eruption. On January 10 and 11, a slight Widal reaction was found. On the day after his admission the temperature fell to normal. On the fifth day the temperature fell below normal, where it remained until January 16, when it rose again to normal. Although the illness was decidedly marked by distinct symptoms and signs of enteric fever, it was of a mild character throughout. Such cases are not common. The writer cites several instances of this disease in which apyrexia has been noted. The prognosis of such cases from the histories which have been recorded would seem to be grave.—*The Practitioner.*

MEDICAL RECORD.

*A Weekly Journal of Medicine and Surgery.*

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, September 16, 1905.

## THE PRELIMINARY REPORT OF THE PNEUMONIA COMMISSION.

In October, 1904, a commission composed of general practitioners, pathologists, and bacteriologists of this and other cities, was appointed at the suggestion of the Health Commissioner of New York, to investigate the subject of acute respiratory diseases. A report of some of the work of this commission, or rather of various investigations undertaken by laboratory workers at the suggestion of the commission, is now published in *The Journal of Experimental Medicine* under date of August 25, 1905.

The commission decided to concentrate attention first upon the bacteriological and clinical aspects of lobar pneumonia. As a preliminary to subsequent work of a seemingly more practical nature, it was thought necessary to determine, for the identification of the species, the character of the pneumococcus as found in cases of lobar pneumonia and also as found in the secretions in the mouths and throats of healthy individuals, including such a study of streptococci as would suffice to differentiate them from the pneumococcus. Among the studies bearing on these points which it was decided to pursue were the following: (1) A study of the occurrence and virulence of the pneumococcus and organisms related to or resembling this, in the human mouth in health and disease; (2) the evidence of variations in virulence of the pneumococcus; (3) the occurrence of the pneumococcus in children's hospitals, homes, and asylums, with a study of the bacteria of mouths before and after outbreaks of pneumonia; (4) the vitality of the pneumococcus under various conditions; (5) a study of mouth disinfection. The method adopted, as stated in the introductory note to these reports, was, first, to secure the cooperation of bacteriologists in various places, who should make independent studies along the lines suggested; and, second, to establish a central laboratory or "clearing house" to which ultimately cultures from various independent workers should be sent for comparative study under a single observer. It was hoped that by the establishment of this central laboratory with its large number of available cultures, light might be thrown upon atypical forms, variations, etc., and greater precision achieved in determining the characters relied upon for identification.

There are nine separate contributions to the report, most of them being the work of two or more investigators—twenty-one in all. We confess to a slight feeling of disappointment that the labors of so many skilled laboratory workers, extending over the greater part of a year, should have resulted in little more than a reaffirmation of what has long been known regarding the pneumococcus and its distribution. The various contributors found the pneumococcus frequently present in the secretions of the mouth and throat in apparently healthy persons, and determined that the organism taken from these parts was virulent for rabbits and mice, though Park and Williams found it seemingly somewhat less virulent than the organism obtained from a person with pneumonia. A larger proportion of atypical pneumococci was obtained from healthy persons than from those suffering from pneumonia. A rather interesting fact developed in this inquiry was that discovered by Norris and Pappenheimer, who found pneumococci present, not only in the secretions of the mouth and throat, but actually in the lungs in practically all autopsies—and this, whether the lungs were normal or were the seat of lesions of various kinds. But the significance of the discovery was considerably weakened by control experiments which made it probable that the organism was carried into the lungs in the fluids collecting in the mouth of the dying person and flowing down the air-passages during the transfer of the body from the hospital ward to the morgue.

In the course of a comparative study of pneumococci and streptococci, made by Longcope and Fox, attention was directed to Rosenow's statement that acid is formed in considerable amount in cultures of pneumococci in pneumonia serum, but not when serum from normal individuals is used. Longcope found that this phenomenon is dependent upon the appearance in the blood serum, under certain conditions, of a substance from which the pneumococcus is capable of forming large quantities of acid. This substance is almost constantly present in the serum during an attack of pneumonia, but disappears after the crisis; what it is and what occasions its presence in the blood during the pneumonic process Longcope was not able to determine satisfactorily. What the practical significance of its presence is in the blood is not yet clearly apparent, but it is probably protective in intention, since acid is inimical to the growth of the pneumococcus. The subject is one that invites to further investigation, and is perhaps the most important as well as novel of all those dealt with in this report.

Some experiments of F. C. Wood, made to determine the viability of the pneumococcus after drying were of interest as confirming what is known regarding the vulnerability of this organism. The diplococcus is tenacious of life when undisturbed in moist or dried sputum kept in the dark, but exposure to sunlight rapidly kills it; oxygen is also fatal to its prolonged existence, for it was found that the organism perished in from one to four hours in powdered sputum even when kept in the dark. In coughing, sneezing, or even talking, the subject of pneumonia, just as the tuberculous, expels many fine particles of saliva or sputum containing great numbers of the specific microorganisms, but the danger to others from this is minimized by the rapid death of the bacteria so expelled under the influence of fresh air and sunlight.

On the whole, we cannot see that the Pneumonia Commission has made much progress as yet toward the discovery of means for the prevention and cure

of pneumonia, which we believe was the object of its composition. The reports of the laboratory workers are of much scientific interest, and we would not deny their value or the necessity of laboratory work in an investigation of this nature, but one must admit that there is not to be found here much promise of a speedy reduction of the shameful mortality from pneumonia in New York and Chicago and some other of our northern cities. Perhaps an unprejudiced study of the methods of the many humble medical practitioners, who do not write much, and who have comparatively little bacteriological wisdom, but whose patients do not usually die from pneumonia, would help the commission toward at least a partial attainment of their object.

## THE BACTERIOLOGY OF THE BLOOD IN TYPHOID FEVER.

In the recently issued Medical and Surgical Report of Bellevue and Allied Hospitals there is an interesting statistical paper by Drs. Warren Coleman and E. H. Buxton (originally read before the New York Pathological Society in February, 1904), containing the results of bacteriological examinations of the blood in 604 cases of typhoid fever, 60 cases of their own and 544 collected from the literature. Only those cases in which large quantities of blood were taken were included. The authors took 10 c.c. of blood from a vein at the elbow, and distributed it among four flasks each containing 100 c.c. of broth. The bacilli recovered were identified both by cultural and agglutination tests. Some bacilli when first isolated were found to react less readily to immune serum than they did after growth on artificial media. This characteristic may persist for several months. The blood contained bacilli in 75 per cent. of the 604 cases. The examinations were made at all stages of the disease. The authors consider this percentage lower than may be expected in future investigations because of the improvements which have been made in technique. Analyzed by week of disease, it was found that of 85 examinations made in the first week the bacillus was present in the blood in 93 per cent. The earliest recorded positive result was obtained on the third day. Of 198 examinations in the second week, the bacillus was present in 76 per cent. Of 115 examinations in the third week, the bacillus was present in 56 per cent. The bacillus usually disappears from the blood by the twentieth to the twenty-first day, but apparently persists for a longer period in more protracted cases. In fact, unusual duration of the disease seems coincident with persistence of bacilli in the blood. The bacillus is not present during convalescence.

It is apparent from these facts, the authors conclude, that typhoid fever is a bacillemia. Therefore attempts to abort or control the disease by the administration of intestinal antiseptics must prove futile. In all but 3 of 21 cases of relapse examined, the bacillus was found in the blood. Relapses therefore seem due to reinfection of the blood.

In 73 of the 604 cases the bacillus was recovered from the blood before the serum reaction could be obtained, but this relation is not mentioned in the majority of cases. The authors believe on *a priori* grounds that bacilli are always present in the blood before the serum reaction occurs. Typhoid bacilli do not form soluble toxins in any quantity—the toxins are liberated from the bodies of dead bacilli—therefore bacilli must be destroyed in the body before agglutinins develop. Again, the serum reaction cannot be obtained before the end of the first week, often in the second and sometimes later, yet the blood contains bacilli in 93 per cent of the cases in the first week.

The authors are rather pessimistic regarding the practical value of the bacteriological diagrams of typhoid fever, for they hold that it can never come into general use, since it requires complete laboratory facilities, and the services of an experienced bacteriologist. This must of necessity render it ordinarily inapplicable in practice outside of the larger cities. But after all the bacteriological diagnosis of typhoid fever is rather a refinement than a necessity in most cases. The general symptoms of the disease are usually clear enough, and confusion with paratyphoid fever (the existence of which as a clinical entity, is denied by many) is practically unimportant, since the treatment of the true affection is the same.

The authors also consider the question whether *Bacillus coli communis* can cause a primary systemic infection with symptoms resembling typhoid fever. They found this bacillus in pure culture in two cases pursuing a mild typhoidal course, but do not feel justified in drawing positive conclusions from such a small number of cases.

## THE SURGERY OF GASTRIC CANCER.

Since Péan performed the first resection of the stomach in 1879, gastric surgery has been widely extended and developed, and although differences of opinion still exist among the internists as to the advisability of operation for dilatation, atony, and displacement, few will deny the advantages extended by operative interference in the presence of malignant neoplasms. The records obtained from operations in cases of carcinoma of the stomach have now accumulated to a sufficient extent to permit of a fairly definite judgment as to the value of the procedure. The publication of isolated cases cannot, however, lead to any satisfactory estimate; this can only be gained from a continuous series done by a single operator or under his immediate supervision. Such a series is available from the records of Prof. Kocher's work in this field, and during the years from 1881 to 1904, about 100 resections of the stomach were performed in his service. Gastroenterostomies are not included in this record, and it seems, moreover, that this palliative operation has been gradually abandoned in favor of the more radical procedure as indications for the latter have been extended. Thus, it appears that as many resections have been done during the last six, as during the previous eighteen years, and, in contrast to this, the number of gastroenterostomies has correspondingly declined. Those cases which have not been previously reported are now collected and commented on by Matti of Prof. Kocher's clinic, in the *Deutsche Zeitschrift für Chirurgie*, Vol. 77, No. 1. The procedure known by the latter's name was usually employed; it consists of a pylorectomy, followed by closure of the stomach and gastroduodenostomy.

In seventy-one operations done by this method out of a total of ninety-seven, there was a mortality of twelve, or 16.9 per cent. Although the latter

figures include a majority of deaths from pulmonary or cardiac complications in greatly emaciated subjects, they compare very favorably with the results reported by other surgeons, and seem to show that resection of the stomach, when carried out under the most careful aseptic technique and by the hand of a skilled operator, is a much less dangerous operation than formerly, and if done early in a patient who is in a good general condition, may be said to be almost without danger. Of seventy-one patients discharged as cured, 28.2 per cent. were living at the time of the report. The average duration of life in those who died from recurrences was about eighteen months, although some lived as long as six years. It was found, however, that the gastric functions were fulfilled almost up to the last in all the patients operated upon.

Matti's paper is of extreme interest and value and will repay more detailed study by those immediately interested. The author's conclusion that gastric carcinoma can be cured by operative means, and that the Kocher method is the more favorable because it restores more closely the normal physiological conditions, will, let us hope, be supported by the results obtained by other operators.

---

### The Naval Medical School.

The demands made upon the medical officers of the navy are of such a nature that a special training in this field would seem to be a matter of necessity. But very few organized attempts to supply this want have been made, as those most interested in providing it found themselves hampered by lack of funds as well as lack of interest. After several unsuccessful beginnings, the Surgeon-General of the Navy finally succeeded in establishing the present Naval Medical School in Washington on a firm basis in 1902, and although at present it offers only a six months' course to those who have been examined and commissioned in the regular naval medical corps, it may later on also be opened to members of the naval militia. The president of the faculty, Medical Director R. A. Marmion, in a recent article (*Journal of the Association of Military Surgeons*, July, 1905) states that the basic principles underlying the scheme of instruction constitute the answer to the question, what are the special requirements of service in the medical corps of the U. S. Navy which the graduates of the lay medical schools do not meet? Experience has shown that there are many who are deficient in hygiene, military surgery, ophthalmology, practical chemistry, bacteriology, and military and tropical diseases. In addition, the naval medical officer has other duties to perform than those of an exclusively medical nature, being an essential component of a military fighting body, and the candidates are therefore given thorough instruction in drills, signaling, physical exercises, tactics, and navigation. The equipment at present employed seems to fill all requirements, and the completion of the new naval hospital connected with the school will also afford opportunity for the much desired clinical instruction. Medical officers on shipboard, especially those of the junior grade, unfortunately in the past did not receive the respect and attention due their position, and consequently there were formerly numerous vacancies in the service. The reorganization of the staff which has lately taken place has rendered more attractive for recent graduates a service in which the opportunities compare very favorably with those in civil practice.

## News of the Week.

**The Cholera in Germany** is apparently under control by the sanitary authorities. The chief danger is from the Russian emigrants, most of whom come to this country by way of Hamburg. Dr. McLaughlin of the U. S. Public Health and Marine Hospital Service has been sent to Hamburg to inspect the emigrants detained there, and Dr. J. F. Donnelly of the Holland-America Line sailed this week with five volunteer physicians, who will examine the Russian and Polish emigrants coming to this country through other ports. The medical men will examine the emigrants both at the frontier and at the ports of embarkation. Upon his arrival Dr. Donnelly will consult with Dr. McLaughlin as to the best measures for warding off the disease. On the Holland-American Line there will be three surgeons on every ship, one each for the first, second, and third-class passengers.

**Yellow Fever in New Orleans.**—The end of the epidemic in New Orleans seems to be in sight. The daily number of new cases is in the thirties, and on Monday of this week not a single death was reported. This was the first day without a death since the fever was officially recognized seven weeks ago. Anxiety is felt more now regarding the country round New Orleans than the city itself. The total number of cases reported up to Wednesday of this week was 2,370, and of deaths 319.

**Yellow Fever at Panama.**—On September 1 there was reported to be but one case of yellow fever under treatment on the Isthmus, and the official figures relative to yellow fever in the Panama Canal Zone continue to show a gradual improvement. During the month of August there were sixteen cases of fever among the entire force, with two deaths. There were fourteen cases of fever among persons resident on the Isthmus other than employees, five of which resulted fatally, making the total number of cases thirty and the total deaths seven. During June there were seventy-two cases and seventeen deaths, of which forty-six cases and ten deaths were among employees; during July twenty-nine cases and eleven deaths, of which twenty-two cases and nine deaths were among the employees. Seventeen of the passengers and crew of the *Mexico*, in from Colon on Monday, were detained at Quarantine, being found to have a high temperature. Most of those returning from the Isthmus with a fever are found to be suffering from malaria, which disease, and not yellow fever, is the real enemy of the canal worker. Fortunately both diseases are fought with the same weapon.

**Militia Officers Admitted to the Army Medical School.**—Gen. Bates, Acting Secretary of War, has recently issued regulations to govern the Army Medical School in Washington providing for the admission of medical officers of the State militia. A surgeon in a militia regiment, in order to be eligible for the course of instruction must not be less than twenty-two nor more than thirty-five years of age. He must be of sound health, good moral character, and a citizen of the United States. He must have been a member of the organized militia at least one year, and must have such preliminary educational qualifications as will enable him to participate profitably in the course of instruction. Militia officers desiring to attend the school must be nominated to the Secretary of War by the governors of their respective States, and the nomination must in each case be accompanied by an affidavit of the nominee, stating his age, citizenship, and length of service in the organized militia, and by a certificate

from the colonel of his regiment or other satisfactory person as to his good moral character. Such militia officers as have complied with the above and who may be selected by the Secretary of War as candidates will be ordered to proceed to posts in the vicinity of their homes for preliminary examination. If the physical examination is satisfactory the candidates will then be examined in the following subjects: Anatomy and physiology; practice of medicine, including therapeutics; surgery; hygiene, general and military. Militia officers, before their admission to the school, must sign an agreement to attend and pursue the course of study and to be bound by and conform to the rules and discipline imposed by its regulations. The expense to the government on account of militia officers attending the school is limited strictly to travel allowances, commutation of quarters, and subsistence. The travel allowances consist of the mileage or transportation allowed by law. Commutation of quarters will be the same as provided by law for officers of the corresponding grade in the army. Militia officers cannot be furnished with quarters in kind. For subsistence each militia officer will be paid $1 per day while in actual attendance at the school. Each militia officer must provide himself, at his own expense, with the proper uniforms of his own State or Territory, and with the required textbooks. The course will require the entire time of the student, so that no outside occupation during the school term will be practicable. When a militia officer graduates from the school the fact of his graduation will be reported to the governor of his State or Territory, who will also be notified in regard to the positions in the medical service of the militia for which the officer is specially qualified. The names of militia graduates will be entered in the register at the War Department as qualified for such duties as the staff of the school may recommend. The course of instruction will be both theoretical and practical and will embrace a period of eight months, commencing on October 1. The course of instruction will embrace the following subjects: Duties of medical officers, medical department administration and customs of the service, military hygiene, clinical microscopy, military surgery, tropical medicine, sanitary chemistry, hospital corps drill, operative surgery, ophthalmology and optometry, military medicine, *x*-ray work, equitation. A satisfactory examination in any subject shall be understood to be the attainment of 80 per cent. of the maximum in both the examination paper and practical work in that subject.

**The Wisconsin Tuberculosis Sanatorium.**—There is considerable rivalry between several towns in northern Wisconsin regarding the location of a State sanatorium. The rather novel spectacle is presented of communities actually asking for the establishment among them of a tuberculosis sanatorium, instead of, as in this part of the world is usual, seeking to prevent it. It is believed that the institution will be established at Cable, Bayfield County, which occupies the highest point of land in the State.

**Adulterated Milk.**—Five grocers in Cincinnati were arrested during the past week for adulteration of milk. Two of those arrested the week before were fined $50 and costs.

**Dispensary for the St. Louis City Hospital.**—The Board of Health of St. Louis has recommended the establishment of a dispensary at the City Hospital. A bill will be prepared and introduced into the municipal assembly providing for the dispensary. A contract has been let for the building of a hospital and dispensary as an annex to the city jail.

**An Organization of English-Speaking Physicians in Mexico** was effected at a meeting held at Torreon on August 20. The meeting was called by Drs. W. R. Jamieson and R. D. Robinson of Torreon, W. J. Lawrence of Mapimi, and W. H. Lloyd of Descubridora.

**The Tri-State Medical Society of Alabama, Georgia and Tennessee** will hold its seventeenth annual meeting in Chattanooga, Tuesday, Wednesday, and Thursday, September 26, 27, and 28, 1905, under the presidency of Dr. H. L. Appleton of Gadsden, Ala. The secretary is Dr. Raymond Wallace, Chattanooga, Tennessee.

**A New Research Laboratory.**—Dr. Morris Herzstein of San Francisco, has purchased land at Pacific Beach for the purpose of erecting a research laboratory for the use of the Department of Physiology of the University of California. It is said to be his intention to deed the property, when complete, to the University.

**California Delegates to the Tuberculosis Congress.**—Dr. F. M. Pottenger of Los Angeles, and George H. Evans of San Francisco, have been appointed delegates from the California State Medical Society to the Industrial Congress of Tuberculosis to be held in Paris the first week in October.

**Action of Copper Sulphate on Animal Life.**—The water of Jamaica Pond in Boston was recently soaked with sulphate of copper in order to destroy an offensive growth of algæ. It destroyed the algæ and also most of the fish in the pond, which have died by thousands and been removed by cartloads for use as fertilizer.

**Dr. S. Susuki,** Surgeon-General of the Imperial Japanese Navy, has arrived in this country to attend the meeting of the Association of Military Surgeons of the United States in Detroit on September 26, 27, and 28. Dr. Susuki was surgeon-in-chief of Admiral Togo's combined fleets from the beginning of the war until after the battle of the Japan Sea, his ship being the *Mikasa,* which has just been destroyed by fire. He comes as official delegate of the Japanese navy.

**Dr. James Francis Donnelly** has been honored by the Queen of Holland with a royal decree entitling him to practise medicine in Holland or in the colonies. Dr. Donnelly, an American by birth, and a graduate in medicine in this city, served as surgeon in the U. S. Army during the war with Spain, and was one of a medical commission of five sent by the government to observe the Boer War. He has been for a number of years surgeon to the Holland-America Line.

**A New and Effective Culicicide** is reported to have been discovered by Dr. Mims, chemist of the New Orleans Board of Health. It is said to be composed of equal parts of camphor and carbolic acid. Dr. White of the Marine Hospital Service, in charge of the fight against yellow fever in New Orleans, has ordered its use by the disinfectors of the mosquito brigade, but advises against its popular employment until further experiments have been made.

**An Act Prescribing the Duties of Physicians and Others Relative to Infectious Diseases.**—The Health Department of Milwaukee, Wis., recently issued a circular letter in which attention was called to the fact that after August 1, 1905, Chapter 102 of the laws of Wisconsin, entitled "An Act Prescribing the Duties of Physicians and Others Relative to Infectious Diseases," will be strictly enforced. Practically all of the communicable diseases are hereafter to be reported to the local health boards. The new list embraces typhoid fever, tuberculosis, erysipelas, chickenpox, whooping-cough, plague, yellow fever, and cerebrospinal meningitis, all diseases which were heretofore not included.

**Hospital for Tuberculosis at Montreal.**—A meeting was recently held in the City Hall, Montreal, to discuss the steps necessary to establish a hospital for the treatment of tuberculosis. It was suggested that an old building, already the property of the city, near Fletcher's Field, be taken for the purpose, but others favored the erection of a new building.

**Medical Inspection of Schools.**—It is proposed to have the schools of Chicago visited by competent medical inspectors, with a view to ascertaining from the schoolchildren the cases of illness in their homes. When such information is obtained the household in which any member is afflicted will be visited, and efforts made to prevent the spread of the disease, and also to improve the sanitary condition. The public schoolteachers will be requested to report all cases of illness to the bureau, and also the addresses of all houses which they have reason to know are not sanitary. The same plan is under consideration in Kalamazoo, where some years ago a medical inspection of the schools was tried, and during its continuance over two hundred cases of infectious diseases, such as scarlet fever, diphtheria, whooping-cough, and so on, were discovered in homes of schoolchildren. The work was abandoned for some cause after a few months' trial, but it is believed that it was the proper policy, and the promoters of the new plan are anxious to have the work, or something like it, begun again.

**Proposed Sanatorium for Milwaukee.**—Plans for the establishment of a sanatorium in Milwaukee county for the care and treatment of tuberculosis are being rapidly perfected. It is proposed to follow the plan of the Wayne Sanatorium, near Detroit. This consists of two tent pavilions, arranged in such a manner that they may be supplied with heat and light from the hospital for the insane. The tents are capable of accommodating about thirty patients in all.

**Street-car Injuries Influence the Mortality Rate.**—Accidents have become so numerous in Los Angeles that they have become an important item in the mortality rate. In a little more than a year and a half 43 persons have been killed and 314 injured.

**Tetanus following Vaccination.**—A death from tetanus following vaccination is reported from the Children's Hospital, San Francisco. This is the second death from this cause and in this vicinity within the past year. The health authorities ought to announce, it seems, the source of the virus, particularly if it was obtained from the same source in both cases. It would be of interest also to know whether the manufacturers of it are also makers of antitetanic serum.

**Rules of Health at Stanford University.**—Stanford University of California has established a commendable rule for the prevention of disease among the students. Beginning with the opening of the fall session this year, each applicant for admission to the freshman class must undergo the usual examination conducted by the physical director of the institution. He must also submit a certificate from the landlord with whom he intends to reside. His physical condition must conform to a standard, and he must reside at a place that has been examined and approved by the Board of Health.

**Football a Science.**—Dr. Benjamin Ide Wheeler, President of the University of California, in an address before the student body at the opening of the fall session, if quoted correctly, said that "football is an advanced science." Probably the species of football to which he referred is indigenous to California.

**Hospital Bequests.**—Mr. W. W. Franklin of Columbus, O., has left $50,000 each to the Children's Hospital and the Home for the Aged of that city, as well as the residue after settling a $700,000 estate. It is thought that each institution will receive about $150,000.

**The North Kentucky Medical Society** held its annual outing at Walton, Ky., August 10. Addresses were made by Rev. Mr. Rodgers of Walton and Dr. J. H. Brown of Crittenden. The ladies of the town provided lunch. Dr. Edwin Ricketts of Cincinnati was toastmaster and toasts were responded to by Dr. C. D. O'Hara of Williamstown, Dr. C. W. McCollum of Erlanger, Dr. J. H. Buckner of Cincinnati, Dr. C. E. O'Hara of Williamstown, Rev. Lafe Johnson of Walton, and Mr. R. H. Elliston of Williamstown.

**Typhoid Fever in Philadelphia.**—There was a steady decline for three weeks in the number of cases of typhoid fever reported to the Philadelphia Bureau of Health. For the week ended September 2 there were but sixty-two cases as compared with eighty-two for the preceding week and 125 for the week before that. An increase occurred, however, during the first week in September, the number of new cases being 152, an excess of 90 over the preceding week. As the increase is chiefly in the parts of the city supplied with filtered water, it is ascribed to the return to town of persons infected while absent on vacation.

**A Tuberculosis Fête.**—A lawn fête was held August 12 at "Rough Point," the residence of Frederick W. Vanderbilt, for the benefit of the Newport Association for the Relief and Prevention of Tuberculosis. The total amount received from all the booths and from individual donations was $16,432.16.

**The Central Wisconsin Medical Association** held its annual meeting at Madison on August 29, under the presidency of Dr. T. Nuzum of Brodhead. The following officers were elected for the ensuing year: *President*, Dr. S. R. Moyer, Monroe; *Vice-Presidents*, Drs. A. C. Helm, Beloit, W. W. Washburn, Milwaukee, John Binnie, Poynette, and W. W. Gill, Madison; *Secretary-Treasurer*, Dr. C. S. Sheldon, Madison.

**New York and New England Association of Railway Surgeons.**—The fifteenth annual meeting of this association will be held at the Academy of Medicine, New York City, November 17 and 18, 1905, under the presidency of Dr. G. P. Conn of Concord, N. H. One-half-day of the meeting will be devoted to a symposium on "Injuries to the Head and Spine." A cordial invitation is extended to the profession. The secretary is Dr. George Chaffee, 338 Forty-seventh street, Brooklyn, N. Y.

**The Summer Meeting** of the Berkshire Medical Society was held September 1 at the residence of Dr. J. Gardner Smith of this city on Pontoosuc Lake, Pittsfield, Mass. About thirty members were present. Dr. William Gilman Thompson read a paper on "An Infection, Following an Attack of Typhoid Fever," and Dr. Charles H. Richardson one on "The Surgical Treatment of Intestinal Perforations in Typhoid Fever."

**The New Orleans Health Association** was organized at a meeting of citizens held on the last day of August, the officers being: *President*, Charles Janvier; *First Vice-Presidents*, Gustave Lehmann, Sr., and Louis P. Rice; *Treasurer*, Wm. Adler; *Secretary*, H. M. Mayo. Dr. Beverley Warner was also made a member of the governing board. The aim and purposes of the association, as set forth in the preamble to the plan of organization, are "to assist in all

measures affecting the health and sanitation of this city; to secure such laws or changes in our present laws, national, state, and city, as will place our sanitary legislation in line with the most recent discoveries in science; strengthen the hands of the health authorities; better enable them to keep out epidemic diseases; to deal efficiently and successfully with such diseases should they break through our lines of defense, and to minimize the panic and business injury resulting therefrom."

**The Orangeburg County (S .C.) Medical Association** was organized at a meeting of about twenty-five physicians on September 5. The organization was effected with the following officers: *President*, Dr. W. L. Pou, St. Matthew's; *Vice-Presidents*, Drs. M. J. D. Dantzler, Elloree, and M. S. Gressett, Branchville; *Secretary* and *Treasurer*, Dr. Lin C. Sheeut, Orangeburg; *Chaplain*, Dr. J. A. Clifton; *Solicitor*, Dr. L. K. Sturkie.

**Dr. D. E. Salmon**, chief of the Bureau of Animal Industry of the Department of Agriculture, resigned on September 6. He has been connected with the department for twenty-one years. Dr. Melvin of Illinois, assistant chief of the bureau, will be promoted to fill the vacancy.

**A Hazardous Occupation.**—Two insurance companies recently refused to give a lawyer of Breathitt County, Ky., a life insurance policy because he was attorney for two noted feud leaders of Breathitt County, and was believed to be in danger as assassination. The agent for the company wrote the application, and the lawyer passed the medical examination, but the officials would take no chances because of the applicant's connection with the feud troubles.

**A New Hospital for Los Angeles.**—The Trustees of the University of Southern California are interested in the suggestion to raise funds by subscription for the establishment of a large hospital, to be conducted in connection with the school of medicine. The idea will be discussed and plans laid at a conference, September 27.

**Obituary Notes.**—Dr. Joseph R. Smith of Birmingham, Ala., died August 30 at the age of eighty-seven years. He was born on his father's homestead, where now stands the town of Bessemer, and was graduated from the Transylvania Medical College at Lexington, Ky., in 1841. He began the practice of medicine in 1843, but retired in 1870 to engage in real estate transactions, in which he amassed a fortune.

Dr. John H. Rhodes of Jackson, Miss., died suddenly on August 30 at the age of forty-five years. He was a graduate of the Louisville, Ky., Medical College in the class of 1882. He was City Physician and a member of the State Board of Health.

Dr. John G. Park of Worcester, Mass., died August 29, following an operation for gallstones, at the age of sixty-seven years. He was born in Groton, and was graduated from Harvard Medical School. During the Civil War he served in the medical service of the navy, and at its conclusion settled in Worcester. He was superintendent of the State Lunatic Asylum for five years, and of the Worcester Insane Hospital for eleven years.

Dr. J. Franklin Ford of Omro, Wis., died on August 28 at the age of fifty years. He was a graduate of the Rush Medical College, Chicago, in 1887.

Dr. William R. Owen of Sublette, Ill., died in Minneapolis on August 27. He was a graduate of the College of Physicians and Surgeons, Chicago, in the class of 1889. He retired from active practice about four years ago.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

ASYLUMS BOARD'S TREATMENT OF DOCTORS—CHAIR FOR PROTOZOOLOGY — STERILIZED WATER FOR TROOPS — LEICESTER MUSEUM OF PATHOLOGY—MIDWIVES' ACT—AMAZING CLAIM FOR COMPENSATION—DRUG HABIT.

London, August 5, 1905.

The Metropolitan Asylums Board has done many foolish things and has in various ways become offensive to medical men. This week the 2d, 3d, and 4th assistant medical officers at the Darenth Asylum have resigned their positions rather than permit non-medical persons to modify their directions as to things exclusively medical. It appears that under the Board, assistant medical officers are ranked as subordinate officers, while the chaplain, steward, matron, and head schoolmistress are principal officers. It is not necessary to consider whether such a classing of officials is a proper one. It suffices to say that none of these principal officials should be permitted to revise the medical directions of the qualified medical men, and yet it is said the intrusion of these lay persons into medical matters is a frequent source of complaint. Such intrusion undoubtedly constitutes a danger to the patients. This week's resignations should bring home to the Asylums Board the absurdity of the position and induce members who retain a sense of propriety or responsibility to insist on immediate change and an apology to the gentlemen who have thus been driven to resign.

The Senate of the University of London, has accepted an offer from the Colonial Secretaries of £700 a year for 5 years to institute a chair of protozoology. The Senate has decided to devote the whole amount to the salary of the professor, and to add to it £200 a year for assistance and laboratory expenses.

The Army Medical Department recently arranged a demonstration of the inventions for supplying troops on the field with sterilized water. Chemical and mechanical methods were shown, but the most attractive plan seemed to be sterilization by heat. There were several inventions for this purpose on show, including one by Dr. Griffiths, and another, perhaps better known, by Dr. Leigh-Canney, who has devoted much attention to the subject.

A good deal of satisfaction has been expressed as to the arrangements of the Pathological Museum at the Leicester meeting. The committee on this occasion seem to have gone about their work with determination to make this year a record one. They gave every help to readers of papers and even to those who took part in any of the discussions, to say nothing of those who examined the specimens as displayed, during the time they could take from sectional work and entertainments. I mentioned in a previous letter that demonstrations were also arranged for. Groups of specimens illustrating pathological conditions of certain organs under different conditions have been much praised. The catalogue of the whole collection is a pamphlet of 75 8vo pages. It is impossible, therefore, to give notes of all the sections, but I have asked some observers to give me something on two or three sections, and transcribe what they say. The gynecological collection is on all sides said to be the best—so first of it.

This exceptionally fine collection contained specimens of three diseased conditions, particularly well illustrated, these were: Extrauterine gestation, cancer of uterus, degenerations of uterine fibroids. Among individual specimens the following appeared to the writer as particularly worthy of notice: An ovarian cyst developing in the stump after ovariotomy from the Royal Free Hospital, London. Section of ovary showing corpus luteum with lutein cells invading the central blood clot. Cervical fibroid and pregnancy, the pregnancy had advanced to about two months. The fibroid was the size of a uterus in the third month of pregnancy, and would have presented an insuperable obstacle to delivery. These were from the Museum of St. Bartholomew's Hospital. Hematometra of life-long standing from a woman aged 42, from St. George's Hospital Museum. Elephantiasis vermucosa of vulva. A mass the size of a cocoanut removed from a girl aged 19, and of congenital origin, from Dr. Maclean, Cardiff. Among the specimens illustrating cancer were those from fourteen consecutive cases of cancer of the uterus, removed by abdominal section; this series was very well mounted, and illustrated all forms of the disease. It came from the New Hospital for Women, London. Another series of seventeen cases treated by vaginal hysterectomy was from Dr. Cuthbert Lockyer, London. One hundred and six was a specimen of adenocarcinoma affecting both ovaries with a metastatic growth in the breast. The tumors of both ovaries and of the breast were shown; they were all removed at the same time. There were some interesting specimens from the Royal Free Hospital, London, showing the relationship of hydatidi-

form mole with lutem cysts of the ovaries, also several specimens of chorion epithelioma. Among the specimens illustrating extrauterine gestation were two of complete decidual casts expelled from the uterus during the course of the pregnancy, and four of the upruptured tubes removed by operation. Among the specimens of fibroid was a particularly good one showing cystic degeneration, from the London Hospital, and several showing the deep red color of necrobiosis or red necrosis. There were some very good specimens of adenomyoma of the body of the uterus, one from the Birmingham University Museum, sent by Dr. Thomas Wilson, in which there was an associated sarcoma of the ovary, and another by Dr. Tate, London, in which the uterus was of the size of one at the third month of pregnancy.

The medicine portion of the exhibits in the pathological museum were well arranged, and both interesting and instructive. They included drawings in color, photographs, radiographs, and jar specimens, illustrating clinical medicine. Especially noticeable were photographs of the different stages of the smallpox eruption, microphotographs of the micrococcus catarrhalis, radiographs of calculi, vesical, biliary, and renal, and of new growths, chiefly of bone, some pictures of skin disease painted in water colors, and several jar specimens of aneurysm of the ventricles of the heart. There were also photographs of leprosy occurring in Arab patients.

The surgical section contained many specimens of interest and importance; amongst these are some excellent skiagrams, notably those shown by Mr. E. Henry Fenwick, of stones in the uterus, and a series of false shadows simulating them, with indications for differentiating between the true and false shadows. A number of prostates removed by Mr. P. J. Freyer, and of diseased thyroids removed by Mr. James Berny, are well worth noticing. Mr. C. J. Bond shows numerous specimens of surgical interest, including, as they do, both photographs and radiographs, whilst a considerable number of specimens have been sent from Cambridge University by Dr. Roderick.

The first prosecution under the Midwives' Act was brought by the County Council on the 13th inst. The defendant had on her brass plate "registered midwife," but she had been refused registration, apparently because she did not apply within the legal period. An appeal on account of poverty was made for her, and it was said she had been in practice 20 years. "What am I to do if my living is taken away," she exclaimed? She could have registered when the act passed on proving she had been in practice one year, and she can continue her practice until 1910, but must not call herself a registered midwife.

A claim for compensation was lately put forward by a Scotch ex-official, which excited no little astonishment. The gentleman asked his town council for £2,320, being £80 per annum since 1875, on account of blindness, which he asserted was caused by malpractice by a doctor who was at the time the chief magistrate of the town.

At a police court the other day, a woman was asked if she was in the habit of taking drugs and replied: "Oh, no." The solicitor said: "But a thousand empty chloroform bottles were found in the house after you left?" and was answered, "Well, I don't see what that has to do with the case."

## OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

ROENTGEN RAYS IN THE TREATMENT OF LEPROSY—MALARIA CLOSES SCHOOLS—SERUM PROPHYLAXIS OF RINDERPEST—IMPORTANCE OF DRAFT ANIMALS TO THE DEVELOPMENT OF THE PHILIPPINES—CHOLERA IN HONG KONG—FREEDOM FROM PLAGUE.

MANILA, July 28, 1905.

IN a letter to the MEDICAL RECORD under the date of October 15, 1904, which was published in the issue of December 3 of that year, mention was made of an interesting experiment that was being conducted at the San Lazaro Leper Hospital, in the treatment of a certain number of lepers with the *x*-ray. Particular mention was made of a case in a male adult who had a leprous infiltration of the left ear, which enlarged it to the extent that its long axis measured four inches, while the ear on the right side, which was normal, measured only about two inches. A few weeks of treatment with the *x*-ray reduced it to normal size, and at the same time other leprous symptoms began to disappear. The subsequent history of the case, was as follows:

The *x*-ray treatment was continued for about one month longer, with the result that the outward physical evidences of the disease disappeared entirely. The change in the affected ear was truly remarkable, in fact, it would have been impossible for the casual observer to see any marked difference in the two ears. The man, however, soon afterward showed evidence of chronic illness. He began to lose weight, and he would voluntarily spend a good portion of his time in bed. During April he began to decline rapidly, and in the early part of July he died.

A very careful post-mortem examination was made, which showed that he had marked atrophy of the liver, and death was in all probability due to that cause. Many sections of tissue were taken from various parts of the body and stained for leprosy bacilli, but so far none have been found. The diagnosis of leprosy, upon his entrance into the hospital, was confirmed by at least three different physicians, and two independent observers found leprosy bacilli in scrapings taken from lesions on the head and face.

From the foregoing, it would appear that there can be but little ground upon which to question the original diagnosis. Further experiments are being made with the *x*-ray in other cases, and the result is awaited with a great deal of interest.

During the week it was reported that some disease was so prevalent in Nueva Caceres and adjoining towns in the province of Camerines, that many of the schools had to close. The Board of Health made an investigation of this matter, and found that the disease was malarial fever. Large quantities of quinine have been forwarded, and the local board of health, as well as the American school teachers in the affected district, are busily engaged in administering the drug.

The real value of serum inoculation, as a prophylactic measure against rinderpest, has received considerable attention of late. The parties on the one side of the controversy claim that the inoculation of antirinderpest serum not only confers an absolute immunity for a period of about six months, but also that it will cure over 60 per cent. of the animals which already have the disease. The parties on the other side of the controversy claim that while it may be true that an immunity is conferred for a period of six months, it would be more economical to segregate the sick animals, and thus prevent the spread of the disease, and to reimburse the owners for all animals that die.

The simultaneous method seems to be the only one which has any real permanent value. This consists of injecting a definite quantity of virulent rinderpest blood into the shoulder of an animal, and at the same time, a fixed amount of antirinderpest serum in the other shoulder. The object of this method is to produce a mild form of rinderpest in the animal, and thereby make it entirely immune against this disease for the rest of its life. In the treatment of the animals of the government laboratories, by this method, the loss on account of the injection was less than 2 per cent. Unfortunately, the use of that method in the provinces is said to have caused a mortality of 50 per cent. in the inoculation of some of the herds. It is claimed that this high mortality was caused by a number of impostors who traveled about the country and represented themselves as Government employees. They charged a fee for their services, and, for a time, are said to have collected a considerable amount of money. They did not practise the rules of asepsis, however, and in many instances other infections were introduced, which caused the death of the animals.

If, in practice, the mortality as the result of the injection can be reduced to 2 per cent., the chances of eradicating the disease from the islands are very favorable. The logical course would seem to be to establish a quarantine station, and to forbid the importation of animals except at one port. In this way, they could all pass through the station, be inoculated, and then they would be ready to be distributed to such places as might be desired. The present method of inoculating all the animals in the vicinity in which the outbreak occurs seems to control the disease for the time being, but this is only a temporary expedient, and accomplishes very little toward stamping out the disease. The money used for this latter purpose would no doubt be better invested in a method that offered more permanent results.

The importance of having healthy animals will be appreciated, when it is remembered that the prosperity of the Philippines depends upon its crops, and in view of the fact that the islands are practically dependent upon either oxen, carabaos, or horses, for transportation, it is obvious that serious consequences must ensue when they are not available in large numbers. Disease among draft animals has probably done more to retard the development of the Philippines than any other one factor.

Last week, a case of cholera made its appearance in Hong Kong. It appears that a Frenchman walked into the hospital one evening, and before any history could be obtained he became unconscious, and soon after died of cholera. The quarantine authorities in the Philippine Islands immediately ordered the discontinuance of shipments of fresh vegetables from the port of Hong Kong. So far, no further cases have been reported, and if this favorable condition of affairs continues, the embargo on vegetables will be lifted at the end of two weeks.

Manila still continues to remain free from plague. The

number of cases for the fiscal year ended June 30, 1905, shows that there has been about one-half as many cases this year, as last. For the year 1904 there were 101 cases, while for the year 1905 there were 51 cases. The following is very encouraging when it is remembered that plague has been occurring in epidemic form in India and other nearby countries.

## OUR BERLIN LETTER.

(From Our Special Correspondent.)

TREATMENT OF PUERPERAL SEPSIS—SUBCUTANEOUS ADMINISTRATION OF IRON—A CASE OF MIKULICZ'S DISEASE—A SEA SANATORIUM—NEW YORK'S PREEMINENCE IN THE FIGHT AGAINST CONTAGIOUS DISEASES—INCREASE OF QUACKERY IN GERMANY.

BERLIN, August 8, 1905.

GREATER activity is manifest in the gynecological section of the Charité. Bumm, its new director, spoke, on July 3, in the Berlin Medical Society, on the surgical treatment of puerperal sepsis. He believes that curettage, extirpation of the uterus, and operations on the tubes and ovaries have proved of no advantage to the patient. But the method of ligating the affected veins in thrombophlebitis and peritonitis has given him good results. In four cases of acute and one of chronic pyemia, he has ligated the spermatic and hypogastric veins, and has cured the patients. The operation should be performed only through the peritoneal cavity, because the view of the field of operation is better in this than in any other method.

Senator recently read a paper on the subcutaneous injections of iron in anemia, after the manner recommended by Italian writers. He said that ferrum ammoniatum used in these injections, produces less pain than the other iron preparations used subcutaneously. Its employment, however, gives no real advantage over the use of iron by the mouth in simple anemia and chlorosis. In the first place, it has been proved that iron is absorbed by way of the intestines, and gastritis excited by iron is very rare; the gastritis is usually the result of the anemia, and is cured with it; in the second place, we do not need to have rapid absorption of iron in an essentially chronic condition like anemia, but we must fear the absorption of poison, and iron acts as a poison to the body when used in this way. The old objection to the taste of iron is no longer valid, in view of the modern preparations with their pleasant taste. From this point of view the subcutaneous use of iron should be reserved for cases in which there is gastric ulcer, in pernicious anemia, leukemia, and pseudoleukemia, and in cases where the stomach rejects all remedies. In thirty cases treated with arseniate of iron no benefit was received, and considerable pain was unavoidable.

At the time when the premature and tragic death of the eminent surgeon Mikulicz has caused deep regret to all medical men, a paper by Buschke, read at the Medizinische Gessellschaft, reminds us that this author was the discoverer of a new disease, which received his name, the swelling of the lacrymal glands. The case presented was that of a man of twenty years, till then quite well, who suffered from an ulceration of the mucosa of both cheeks. Swellings of both temples followed. At the end of five months, on the inside of the left cheek was a flat ulceration, with a whitish surface. Over both temples were to be seen large, solid tumors, not movable, and not sharply defined. Histological examination showed them to be composed of lymphoid tissue. Under the use of arsenic the left tumor disappeared, and the right was much reduced in size. The diagnosis seemed doubtful.

In the Verein für innere Medizin, Hans Leyden read a paper on the seagoing sanatorium. He sketched such a hospital thus: An auxiliary steamship is to be preferred to a sailing vessel. It should have a speed of from twelve to fifteen knots an hour. In such a boat there is better lighting and ventilation; it has a more even motion, and can escape more easily from a contrary sea. The sanatorium should be arranged for not more than 150 inmates, so as to secure the best treatment and the most harmonious life among the patients, and the greatest economy in the arrangements of the ship. There should be two large windows on the cross at give light to the cabins. Each person should have fifteen cubic feet of air space. The [illegible] should be easily disinfected. The berths should be arranged lengthwise of the ship and freshness should enter at one end and be drawn out at the other. There should be a complete operating room, a hall for gymnastics and massage, apparatus for electric and all other kinds of baths, etc. There should be dining, music, and smoking rooms, and all should be connected by wide promenade passages and stairs. There should be reclining chairs for those that cannot walk. To prevent tediousness there should be lectures on zoology, astronomy, the use of the sextant, and arrangements for photography, fishing, and other amusements. Two physicians should have all the superintendence, and a voyage of six weeks is the best length for treatment. The best regions are the northeast portions of the Atlantic, the Mediterranean Sea, and the West Indies. The only objection made during the animated discussion that followed which need be mentioned is that such a comfortable ship sanatorium could be of value only to millionaires. The North German Lloyd line has calculated the expense of living on such a ship, and has found that it will be much less than that of a voyage on the excursion yacht the *Victoria-Louisa*, of that line.

In a paper read before the Berlin Medical Society a short time ago, Wassermann asserted that New York leads all other cities in the fight against infectious diseases. We must know, at the end of an infectious disease, whether the cause of the infection has been removed; to this end, expensive and tedious bacteriological examinations must be made, for which the general practitioner has not time. New York City has a municipal laboratory for such work. The lecturer was seconded by the opinion of all present, when he said that New York should be, in this respect, an example for other cities. A less commendable imitation by the Germans of alleged American practices is in the large number of quacks, which increases daily. According to a report published by the ministry, there are 5,178 quacks in Prussia, against 4,100 of the previous year. In Berlin were recorded 2,875 regular physicians and surgeons, and 1,013 quacks. These numbers speak for themselves without comment.

## Progress of Medical Science.

*Boston Medical and Surgical Journal, September 7, 1905.*

**Applied Anatomy of the Frontal Sinus.**—A careful study of this sinus has been made by H. P. Mosher, who speaks of its size, the characteristics of its mucous lining, and vascular nervous supply. He finds that the prolongations of this cavity are very variable, but that the imperforate septum between them is practically constant, there being but one exception in one hundred skulls examined. In addition to this median septum, partial septa often exists in each cavity. Each wall, anterior, posterior, floor, orbital, and nasal portions, is fully described. Concerning catheterization of the sinus, the author declares that it is almost always necessary to remove the anterior end of the middle turbinate. The catheter should be bent at an angle a little over or under 90 degrees and introduced between the anterior end of the middle turbinate and the ethmoid bulla. It is then brought forward and rotated outward until it engages in the groove of the uniciform. The handle is then depressed, and if the front nasal duct is continuous with the groove of the unciform, as is the case once in four instances, the catheter glides into the sinus, but if the groove of the unciform ends blindly the catheter brings up in this pocket or in an anterior ethmoid cell. In the majority of cases the catheter breaks through the base of this ethmoid cell and thus enters the sinus.

**Causes of Disability After Fractures of the Lower Leg and Ankle.**—F. J. Colton believes that avoidable *disabilities* are nearly all due to one or more of three causes: (*a*) failure to maintain or restore the general long axis of the leg, whether local deformity is much or little; (*b*) mechanical damage to the ankle joint or change in its plane, and (*c*) loss of joint motion from rigidity of muscles and tendons. In the series of special cases studied by him the following conditions were variously found, viz., displacement of the bone ends, change of the leg axis, damage to joints interfering with their bony mechanism, arthritis (traumatic), static flat foot, not from deformity but following over-use of traumatic muscles, and contractures. These various causes are taken up in detail, some simple diagrams illustrating the author's various propositions. In regard to the prevention of the unfavorable results frequently occurring, he notes that in the first place the tendency to malposition must be guarded against, first, by careful study of lesions and by careful reduction; secondly, by careful review (checked if may be by *x*-rays) of the result of reduction and of the present condition—a review to be made after not over two or three weeks, when swelling and spasm are gone yet while correction of mistakes is still easy. Later, operations are the only resort;—undesirable, yet they are often of great service. The purely static troubles independent of malposition are usually readily relieved by careful plate-support. The contractures are, Colton believes, avoidable in all cases unless there is long continued tendency to recurrence of deformity or delayed union, or extreme trauma affecting soft parts as well as bone. They call for treatment directed toward preserving flexibility and nutrition of the muscles, instituted before fixation has rendered the early spastic changes permanent.

*New York Medical Journal, September 9, 1905.*

**Notes on the Death Rate of Infants in the Summer Months.**—The figures and deductions of F. L. Wachenheim are based on studies of the New York Health Department tables for the boroughs of Manhattan and the Bronx during the months of July, August, and September of the last fourteen years. Allowance is made for temperature variations which are reduced to a true mean. The figures show a mortality reduction of from 84 to 56 per cent. of infants under one year. The decline has been most noticeable in recent years but has been most irregular in its progress. The high mortality for certain years is not easy of explanation. Since 1901 the reduction of mortality has not been maintained. The unusually cool summer of 1903 did not give as good a record as might have been expected, while the results of 1904 are far from flattering. The author acknowledges the good work of the Health Department, though he suggests that the bad showing of one special year, that of 1898, was due perhaps to the dismissal of a great part of an experienced staff as one of the mutations of city politics, and the substitution for these trained men of inexperienced physicians. The corrected statistics show that hot weather alone does not play the chief rôle in producing a high infant mortality, but they also prove, however, that with proper prophylactic measures our worst summers may be rendered comparatively innocuous.

**The Hot Air Treatment of Acutely Inflamed Joints.**—The paper of W. R. Thomson is a plea for the more common use of dry hot air in joint affections in the acute stage, and he has found that "baking" affords very prompt relief in this class of maladies. The patient does not find the heat uncomfortable, but on the contrary the relief is so marked that he frequently obtains his first sleep while undergoing the treatment. The author declares that a case of articular rheumatism seen during the first three days will almost invariably be cured after three bakings. A case seen after six weeks of various plans of treatment may require fifteen or more bakings before recovery is in sight. He does not include chronic arthritis and joint adhesions in his category. His method of applying the oven is thus described: If the patient is in bed, he is generally propped up if a shoulder is the affected point, otherwise he is allowed to lie down or sit up as best suits him. If a hood is to be used, one thickness of bath toweling is sufficient, but if the part is to be placed directly in the oven he generally uses three layers of toweling and a thick pad under the most dependent part. Instead of swinging the limb in a hammock made of canvas he prefers one of strong fish net. Every portion of the body exposed to the heat must be in close contact with bath toweling, care being taken that there are no tight bands and that the pad on which the arm or the heel rests is very loose and soft. Séances generally last one hour, during which the patient sips water slowly. After baking the parts should have a red and white mottled appearance. The parts are then bathed in warm grain alcohol, or camphor spirits, and carefully dried. Possible dangers are burning and collapse, but the author has never met them. Illustrative cases are summarized.

**The Relative Frequency of a Protruding Lateral Sinus and Its Bearing on the Choice of Method for the Total Opening of the Middle Ear Cavities; With Demonstrations of Anatomical Specimens.**—The question is discussed by E. Amberg, who exhibits photographs of specimens and gives measurements and a diagram to illustrate his various propositions. The results of his investigations lead him to believe that a lateral sinus can be regarded as displaced forward if it approaches the suprameatal spine more than ten and six-tenths mm. He suggests also that disturbances often arising after the packing of a protruding lateral sinus may find their explanation in the local anatomical conditions. His diagram and description thereof must be consulted in the original paper by those interested.

*Medical News, September 9, 1905.*

**The Recognition and Treatment of Pancreatic Inflammation.**—Carl Beck believes that pancreatic inflammation is more common than is generally supposed. He describes the anatomical relations of this organ, but declares that our knowledge of the symptomatology of its various affections is still very imperfect. The deep situation of the gland and its close environment to neighboring organs render exact diagnosis very difficult. Physiology helps us some, for we may make a diagnosis of pancreatic trouble from the cessations of its functions, as shown by fatty diarrhea and diabetes. If, while biliary disturbances are absent much fat is found in the feces, pancreatic disease may be suspected. Sugar in the urine corroborates the diagnosis if other symptoms point to this organ as the one at fault, but the absence of sugar under similar conditions proves nothing against the tentative diagnosis. Pain and cachexia are too indefinite symptoms to afford us much assistance. Chronic jaundice complicated with considerable enlargement of the gall-bladder and without colicky attacks in the biliary sphere should lead to a suspicion of diseased pancreatic head. In thin individuals palpation may give us a clue to the seat of the malady. The present status of abdominal surgery suggests the opening of the belly in these doubtful cases. Cures have been reported in patients whose inflamed pancreatic glands were exposed by laparotomy and left untouched. The author has had three cases of the acute form of inflammation. Of these one recovered. In none could an accurate diagnosis be made before abdominal incision.

**The Pneumococcus as a Factor in Hemoptysis.**—This topic is considered by L. F. Flick, M. P. Ravenel and J. W. Irwin. They note the absence of any assigned reason for the epidemicity of hemorrhage in tuberculosis. Theoretically they were led to believe that if any germ had to do with it the pneumococcus would be the most probable one, and they have therefore studied the ejected blood of a number of cases in which the pneumococcus was found. The streptococcus was also present in most of the cases. They do not feel justified in drawing any conclusions from so few cases, but declare that if it shall be proven that the pneumococcus is responsible for hemorrhages in tuberculosis, we shall have to change our views about the etiology and treatment of this special symptom and shall probably be able to prevent its occurrence to a much greater degree than formerly. As between the relative importance of the pneumococcus and the streptococcus in their findings, they say that the former has been vastly the predominating organism in every instance except one.

*American Medicine, September 9, 1905.*

**Difficulties in Abdominal Diagnosis.**—E. E. Montgomery recounts the history of six cases, illustrating some of the difficulties, which may be divided into those in which the solution has to do with the existence or nonexistence of pregnancy; those in which ovarian tumors may be in question; those in which doubt occurs as to the presence of a myoma, and those in which there is uncertainty as to the existence of other growths.

**Deformities of the Lower Extremity.**—Gwilym G. Davis says the main characteristics of these deformities is weakness. This may be either a weakness affecting the constitution and tissues of the body generally, or it may be a local weakness, or it may be both combined. For purposes of discussion he divides them into three classes: (1) Those due to rickets; (2) to paralyses; and (3) to deformities of the feet. In these three groups are included most of the deformities of the lower extremities; their diagnosis, prognosis, and treatment being considered in detail.

**Therapeutic Value of the Digestive Ferments.**—Henry Wald Bettman reviews the existing beliefs regarding the therapeutic value of the digestive ferments. The exact physiological value to the system of gastric digestion has never been made clear. It is now known that the quantity of pepsin in the stomach does not run a parallel course with the quantity of HCl. Pepsin is more resistant to disease than the other gastric secretions. In many disorders, however, the quantity of pepsin is below the normal, or pepsin may be entirely absent. In these cases the administration of pepsin would seem theoretically indicated. In practice, the administration of pepsin rarely does good in chronic cases. Some patients are temporarily benefited. In France many favorable reports have been published regarding the administration of dog's gastric juice. It is highly probable that animal gastric juice acts merely like a corresponding solution of HCl and pepsin, and that equally good results could be obtained by giving HCl in corresponding doses.

**Iron Precipitates in the Blood, Spleen, and Marrow.**—Edward T. Williams in discussing this subject says that Quincke in a series of articles on Pernicious Anemia found granular precipitates of iron sulphid in the liver, spleen, and bone marrow, and sometimes in the kidneys and pancreas of persons who had died of this disease, by treating sections of these organs with solutions of ammonium sulphid. On treating similar preparations with potassium ferrocyanide, dark blue precipitates of iron ferrocyanide (Prussian blue) were obtained. Dr. Williams found the same precipitates in healthy spleens, marrow, and healthy blood. Ammonium sulphide, which throws down persalts and protosalts of iron, always gives the most abundant precipitates. Potassium ferrocyanide, which throws down only the persalts, gives less numerous precipitates. Potassium ferrocyanide, which acts only on the protosalts, gives the smallest precipitates of all; which shows that the iron exists in both forms, though chiefly as persalt. Dr. Williams believes the gastric juices extract this iron from the food in the form of a chloride, which combines with the peptones in the stomach to form a peptonoid. Thence it passes into the portal vessels and spreads through the system. A large amount of it is plainly deposited in the spleen and marrow, where it is intended to serve as a pabulum for the young red blood corpuscles.

**Advantages of the Sanatorium Treatment of Tuberculosis.**—F. M. Pottenger believes patients can be treated best in a sanatorium because (1) they are under the immediate and constant guidance and control of the physician, who can see that they do the things which are necessary to help bring about a cure, and prevent them from doing things which tend to lower vitality and retard progress. (2) They are furnished with apartments suitably lighted and ventilated, and with food adapted to their needs and properly prepared. (3) They can be given the advantages of all scientific measures which have proved of value in treatment. Good food, fresh air, and careful guidance are the basis of treatment, but the tuberculous individual is not receiving the best that can be had until we give him the benefit of all scientific aids, and of these especially to be recommended are: hydrotherapy, the chemical rays, culture products, and direct medication of the upper air tract.

*Journal of the American Medical Association, September 9, 1905.*

**The Principles of Life.**—M. L. Price, after criticising Metchnikoff's well-known theory of senility, finds only three theories that will properly account for the condition: First, that the failure of the cells is due to successive and repeated inflammations, causing the replacement of the proper cell substance by scar tissue incapable of assuming its functions. Second, that the failure of the cell is a nutritive one, the cell becoming unable, with the advance of time, to keep up the metabolic processes needed in its special functions. Third, that the cell failure is due to the loss of properties enabling it successfully to resist the constant activities of pathogenic organisms and toxins. There are objections to the first of these; senile changes occur evidently without reference to prior inflammatory conditions, and it does not satisfactorily account for the loss of the power of reproduction and regeneration. There is, however, a failure both of nutrition and resistance in senility, and the author offers the theory that the cell is endowed very early in its existence with a specific substance, the presence of which is essential to its functions, that this substance becomes progressively exhausted during the life of the organism, and that it alone, of all the materials of the cell, is not renewed after a certain early stage of its existence. This hypothetical substance he calls bioplasmine, and he represents the probable constitution of its molecule by a graphic formula. He discusses at length the properties and action of this substance in growth, heredity, etc., and speculates on the possibility of its isolation and the possible practical results. The first advance to be made in prolonging life would, he thinks, be in stimulating the activities of the bioplasmine in giving off the substances necessary for metabolism when this can no longer be accomplished by the physiological stimulus. It is not likely, he says, that the bioplasmine molecule is ever so much reduced during life that there is not a considerable amount of these substances in combination. It is to the physiological chemist, he states, that we must look for the clearing up of the problem of the prolongation of life, and it is not too much to expect that our descendants [illegible] hence may realize or exceed the ages of the patriarchs of the Mosaic chronicles.

**The Metabolism of Atrophic Children.**—A. H. Wentworth gives the results of his study of the metabolism of atrophic infants which was awarded the Dalton Prize by the Massachusetts General Hospital. After pointing out the possible sources of error, avoidable and unavoidable, in such research, he reports the details of his [illegible] methods of analysis and controls, which were very careful and complete. The study included two observations of four days each, on each of two children; in one case a post-mortem was obtained several months after the last study, but says that while metabolism observations have established a number of important facts, such as failure of absorption of certain kinds of food, they do not explain the causes of this failure. What has been done shows that the cause or causes of infantile atrophy is not to be discovered by metabolism investigations, and that this must be left to other lines of research.

**The Pathological Effects of Alcohol on Rabbits.**—J. Friedenwald publishes the results of a study of the effects of alcohol on rabbits. One hundred and twenty rabbits were utilized, and the observations extended over a period of several years. The smallest weekly dose was 20 c.c., the largest 50 c.c. The animal that lived longest consumed over 10 liters of absolute alcohol, another consumed over 18 liters of whiskey. There was a marked difference in the susceptibility of different animals, some dying after a few doses, others surviving for years. Young and small rabbits and pregnant females seemed most susceptible. The animals usually gained somewhat in weight at first; this was followed by a stationary period, and then a rapid fall preceding death. During intoxication, the temperature fell 1 to 1.5 degrees. The blood examinations showed a fall to half the normal in the percentage of hemoglobin, but no marked change in blood cells till just before death. The gastric free hydrochloric acid decreased under the influence of the alcohol, and in some cases albumin and casts were found in the urine; in some cases in which these were not found the autopsy revealed kidney lesions. Alcohol evidently has a marked tendency to produce abortion in rabbits. Out of a series of thirty-eight pregnant rabbits, twenty died of septicemia following abortion, and the organism of rabbit septicemia was found in all, though they had been thoroughly isolated from one another. Of the rest, nine had constant abortions, none coming to full term. Three had normal deliveries, but the young all died a few days after birth. Complete autopsies were made in all cases. The lesions found were fatty degeneration of the heart muscle, which was lacking in animals killed after cessation of the use of alcohol, showing that it was not a permanent condition; fatty lesions of the liver and kidneys were also observed in some cases, and occasionally liver cell necrosis, singly or in groups. The experiments failed to produce satisfactory genuine hepatic cirrhosis, though the liver was found more or less cirrhotic in a few instances. Fatty degeneration of the kidney tubules, thickening of the vessels, and atrophy of the glomeruli were noted in a number of cases; in others no changes were observed. Evidences of gastric ulcerative processes were seen in a few instances, congestion was more common. The intestines were usually normal. The testicles frequently showed a diffuse fine deposition of fatty granules in the epithelium of the tubes and interstitial cells. The most notable changes in the brain, as reported by Dr. Berkley, were atrophy of the cortical cells, which was apparently quite marked.

**Pulmonary Streptothricosis.**—T. G. Ashton and G. W. Norris report two cases of streptothricosis of the lungs, and review the literature of the condition. They remark that one reason that this condition is not more often recognized is because it is not readily demonstrable by the ordinary carbolfuchsin method of sputum examination. The microorganism has been found in many cases only after the Gram method has been employed, hence, in suspected tuberculosis, when the tubercle bacillus is lacking, recourse should be had to this method. Of course the mere presence of the streptothrix in the sputum or tissues does not necessarily prove it to be the primary infection. It may be secondary, but there are cases in which this has been shown to be the main and probably the sole agency. The tendency to metastasis, especially in the acute bronchopneumonic type is remarked, the skin and brain being the most frequent localities, but other tissues and organs have also been involved. Clinically, streptothricosis of the lungs appears in two forms, the acute bronchopneumonic form, pyemic in its later stages, and the chronic form, first described by Flexner, which is clinically almost identical with pulmonary tuberculosis. In both cases reported, the patients were treated by stimulation and nourishing diet, and one decidedly improved, and left the hospital. The other, under the same treatment became progressively worse, the infection being apparently more virulent. A tabulated statement and analysis of the published cases is given. The article is illustrated.

*Berliner klinische Wochenschrift, August 21, 1905.*

**The Relation of Hypoleucocytosis to the Bone Marrow.**—Gütig records a case of marked leucocytosis in a girl of eighteen years, associated with tuberculosis of the lymph nodes and of the spleen. In the bone marrow and nodes a high degree of lymphoid hyperplasia was present, in the former the lymphoid tissue occupying both epiphysis and diaphysis. The blood picture showed a relative as well as an absolute decrease in the number of polynuclear neutrophiles that were the only leucocytes in the blood containing granules. Twenty-four hours before death these also entirely disappeared from the circulation, the small lymphocytes constituting 99 per cent. of the leucocytes. The erythrocytes and hemoglobin were both reduced to one-quarter of the normal amount. Clinically, the symptoms were anemia, diarrhea, and increasing weakness, a splenic and an hepatic tumor, and slight enlargement of the cervical lymph-nodes. Death occurred from inanition. Preparations made from the marrow of the ribs and femur showed normoblasts and normocytes, but the preponderating form was a cell with basophilic homogeneous protoplasm in which no nucleus could be demonstrated. Transition forms to typical lymphocytes in one direction, and to a large mononuclear cell with lightly staining, basophilic, homogeneous protoplasm in the other were also present. A few cells of this type contained eosinophile, less often neutrophile, granules. No myelocytes were found. Gütig believes two factors to have been active in producing this symptom-complex. In tuberculosis a hypoleucocytosis is common, the bone marrow contains fewer granular cells, the myelocytes being especially diminished in number. Whether this is the result of the inhibitive action of the bacteria or of their toxins upon the marrow, the seat of elaboration of the granules of the

leucocytes, has not yet been definitely determined. Secondly, the centers in which these granules are formed may have been replaced by the lymphoid hyperplasia, as in pseudoleukemia and chronic lymphatic leukemia, in both of which there is, as in Gütig's case, a relative lymphocytosis at the expense of the granular cells.

**The Early Determination of Bacilli in Pulmonary Tuberculosis.**—Blume finds a rapid decrease in the advanced cases of phthisis in Denmark, with a corresponding increase in incipient apical affections. In the latter group sputum is usually either absent or too scanty for satisfactory examination. Under these conditions Blume orders the patient to cough on eight to ten successive mornings against an ordinary microscope slide held in a wire frame. At the end of this period the slide is examined in the usual way. The writer has thus been able to demonstrate tubercle bacilli when the clinical symptoms were in themselves insufficient for the establishment of a positive diagnosis. Only typical forms may be considered diagnostic.

*Münchener medizinische Wochenschrift, August 22,* 1905.

**The Occurrence of Spirochætæ in Syphilis.**—Rille and Vockerodt have succeeded in demonstrating *Spirochæta pallida* not alone in primary lesions of the genitals, flat condylomata, and inguinal nodes, but also, and for the first time, in extragenital primary lesions, in papules between the toes, in lenticular syphilides of the trunk, in dry scaly syphilides of the scalp, neck and arm, in psoriasis palmaris, and in the mucous plaques of the tonsil. They assume from analogy to the typhoid roseola, that the spirochetes must also be present in the primary roseola, but in this, as well as in the blood and cutaneous eruption of syphilis in the newborn, and in an osteoperiostitis gummosa of the bones of the skull, no organisms were found. In lesions of the lips and vulva in a case of seven to nine years' standing atypical forms of *S. pallida* were found, the first recorded case of their presence in tertiary lesions. To secure thin spreads free from obscuring tissue particles the authors recommended forcible removing of the surface of the ulcer. An abundant exudation of clear serum follows. Giemsa's stain (1:10) yields the clearest pictures. The preparation is to be fixed for ten minutes in absolute alcohol, stained in the Giemsa solution from four hours to overnight, washed thoroughly in water, dried, and mounted. In searching for the organisms fields containing red blood cells are to be selected, as the spirochetes are most often found in contact with or lying upon these cells. Only a spiral organism with six to eight turns may be regarded as *S. pallida*. Disinfection of the wound surface before the examination, as well as local treatment with mercury, does not influence the form of the organisms, but makes the examination easier through the destruction of other bacteria.

**The Action of Radium Upon Pathogenic Bacteria and Infected Wounds.**—Werner exposed cultures of strepto- and staphylococci, bacterium coli, and bacillus tuberculosis to the action of radium bromide. The effect varied with the intensity and duration of the exposure. Fresh streak cultures were far more readily hindered in their development than those in which growth had already begun. Irrespective of their virulence an exposure of thirty-six hours or longer was required to kill the organisms. Such dead cultures injected into rabbits produced both antitoxic and bacteriolytic sera, although their toxins and endotoxins were so weakened that the lethal dose was increased two- or threefold following the exposure. Upon fresh bleeding wounds or upon granulating wounds into which bacteria were rubbed so vigorously as to cause bleeding, radium exerted no disinfectant action. Granulating surfaces are normally resistant to bacterial infection. There is a latent period in the development of organisms in such wounds during which exposure to radium may result in their destruction and in the prevention of infection. The writer concludes that radium is impracticable as a disinfectant both because bacteria are more resistant to its action than the body cells, and because it possesses feeble powers of penetration. Werner further finds that tissue, become necrotic through exposure to radium, exerts a bactericidal action. This is not alone dependent upon the destruction of lymph and blood channels preventing absorption, but also upon the direct action of the necrotic cells upon the organisms. The most important rôle is played by lipoid substances liberated by the dead cells, especially lecithin that is decomposed into its constituents, cholin and glycerinophosphoric acid, both of which are bactericides. The leucocytes in the necrotic area and other substances, some of which are probably ferments, aid in this process of self-sterilization. Autolysis of necrotic tissue in vitro is not attended with the destruction of bacteria, unless the tissue is exposed to radium. The attempt to prepare extracts with antiseptic properties from tissues that had been exposed to radium was unsuccessful.

**The Treatment of Hyperidrosis Plantaris in the Army.**—Villaret urgently opposes the use of formalin in this condition. The application of even a dilute solution of this drug causes destruction of the epithelium in the ducts of the sweat glands with damming back of their secretion. Repeated applications dehydrate the skin, destroy the sweat glands, and leave the skin of the foot abnormally dry, hard, and cool. Not the sweat itself, but the constituents into which it is decomposed when evaporation is prevented, cause the excoriation of the skin. Particularly is this true of the organic acids. A rational therapy must be based upon the prevention of this decomposition, and this object is satisfactorily obtained by the use of salicylic acid that is a non-toxic disinfectant. Villaret suggests the possibility of a vicarious action on the part of the sweat glands in cases of renal insufficiency. This would, if substantiated, constitute a further argument against the employment of any substance tending to destroy the sudoriferous glands.

*Deutsche medizinische Wochenschrift, August* 24, 1905.

**The Abnormal Growth of Epithelium in Wounds and Traumatic Epithelial Cysts.**—Pels-Leusden believes that not alone the superficial epithelium of the skin, but also that of the sweat and sebaceous glands as well as of the hair follicles form a matrix for the proliferation of epithelium in the skinning over of wounds. The epithelial lining often found in tuberculous sinuses is probably a prolongation of the skin epithelium, but the writer has found a similar lining in superficial tubercular abscesses that had not yet formed a communication with the surface of the body. That the denuded cutis may receive a new epithelial covering from these appendages of the skin has already been shown (Rosenblaht). In the closed tubercular abscesses above mentioned, Pels-Leusden again derives the epithelial lining from the epithelium of the cutaneous glands. It seems probable that the sudoriferous glands play the most important rôle, since their convoluted extremities lie deeply imbedded in the fat of the cutis. The author rejects the theory that traumatic epithelial cysts arise from the healing of the skin over an area of epithelium and cutis depressed beneath the surface by the traumatism. In the palm of the hand, where these cysts most commonly occur, the skin is particularly dense and resistant. He ascribes these cystic tumors to a proliferation of the epithelium of the glandular appendages of the skin, due to the irritative influence of a foreign body. Such a foreign body may be absorbed or overlooked at operation. It is possible that the fatty acids may act as such, or a blood clot following a traumatism, especially when the continued use of the hand prevents the union of the edges of the wound. Experimentally the writer reproduced these tumors by inserting plates of magnesium into the cutis of rabbits' ears. The plates were gradually absorbed, leaving behind cysts that in the earlier stages showed a partial epithelial lining, and in the later stages were completely lined by an epithelium in which all the strata of the normal structure were reproduced.

**Spirochæta Pallida in Hereditary Syphilis.**—Reischauer was able to demonstrate this organism in spreads from the liver, lungs, and spleen of the stillborn child of a luetic mother. The spirilla were most numerous in the liver, in which the pathological lesions were more advanced than in the other organs. Neither the kidneys nor the blood contained spirochetes, nor were any found in sections made from the various organs. Giemsa's stain gave the best results in the preparations. Reischauer recommends this stain for the demonstration of bacteria of all kinds, whether in spreads or in sections. In the latter clearer pictures, especially of Gram negative organisms, were obtained with Giemsa's stain than with Loeffler's methylene blue.

*American Journal of the Medical Sciences, August,* 1905

**Notes on Otic Epilepsy.**—B. Alex. Randall considers that many of the epileptiform seizures attributed to ear troubles are of an hysterical nature. On the other hand, some cases seem to be relieved by ear treatment alone. The author reports the case of a boy of eight years of age, who had a drum ruptured and an inflammation of the middle ear set up by a sudden douche in the ear from a hose. He had epileptiform attacks as often as three or four times daily. They consisted of winking, rigidity of the back and limbs, with some twitching of the limbs, and apparent unconsciousness for a few seconds, after which he would go on playing as if nothing had happened. He had a polypus in the left auditory canal, caries of the ossicles, and later mastoid involvement. The ossicles were removed, and the mastoid drained. When the ear was healed the attacks decreased much in frequency and severity. At last report the child seemed to be entirely cured.

**An Unusual Case of Edema of the Glottis.**—Emil Mayer reports the following case: The patient had a history of chronic cough, with mucopurulent expectoration, never bloody; no night sweats or dyspnea; had never had syphilis; voice had always been clear. His illness commenced suddenly with pain in the neck and dyspnea, which went on rapidly to extreme dyspnea and cyanosis, respiration four-

teen per minute, heart rapid and forcible, profuse mucous discharge from mouth and throat, and fetid breath. Laryngoscopical examination showed a large, glistening mass at the base of the tongue, on the right side, filling the entire pyriform sinus, and extending over the epiglottis, so as to leave little space for breathing. A deep incision into the mass set free a quantity of thick, bloody, ill-smelling fluid, and a spray of adrenalin, 1:5,000, was then applied. Distress was promptly relieved, and all inspiratory difficulty ceased on the second day. There was then a large, whitish slough where the edematous mass had been. Examination of a portion of this mass showed staphylococcus albus and streptococcus. A solid mass of new growth took the place of the slough, lying in the pyriform sinus, covering three-fourths of the epiglottis, but not interfering with breathing or swallowing. A portion removed showed nothing but connective tissue. More than half of the epiglottis had sloughed away; the remaining portion of it stood straight up and was adherent by two bands to the lateral pharyngeal wall. The author believes that this was a case of edema of the glottis engrafted on a case of hereditary syphilis of the epiglottis, which had never produced any symptoms but that of cough.

**The Lymphatic Drainage of the Faucial Tonsils.**—George Wood Bacon tells us that of the germs that enter the system by way of the tonsil, those whose vitality is sufficiently great penetrate the epithelium and pass into the interfollicular tissue. Most of those that get into the crypts are destroyed by the polymorphonuclear leucocytes. The absorption of foreign bodies by the tonsils depends on the action of the throat muscles, and the presence of the lymph current in the tonsil. There is a constant production of lymphoid cells in the follicles. They may be looked upon as being in constant motion, passing from the follicles in the direction of least resistance. If the epithelium has been weakened the lymphoid cell breaks through and passes into the crypt, but usually they pass into the lymph spaces of the tonsil and into the efferent lymphatics. A foreign body having entered the tonsil is carried along with the lymphoid cells. Microorganisms, if motile, may enter of themselves, or they may enter by their growth. The last is the usual way for pathogenic organisms. The author, by injecting the tonsil, endeavors to show how these substances are carried by the drainage of the tonsil. The cervical lymphatic glands are superficial, or collecting glands, and deep or terminal glands. The superficial form a collar around the upper part of the neck; they are the suboccipital, mastoid, parotid and subparotid, submixallary, submental, and retropharyngeal. The terminal glands form a perpendicular chain beneath the sternomastoid, and several subsidiary chains. The efferents of all the collecting glands empty into the deep chain. The external chain is continuous with the glands occupying the supraclavicular triangle. The internal chain is along the internal jugular vein. There are many anastomoses between the two chains. The external glands receive the afferents from back and top of the head and neck; the internal group receive the afferents from the front of the head and neck, mouth, pharynx, larynx, and thyroid. The tonsils were injected with a blue fluid, into the lymph spaces, passing through the lymph radicles into the lymph vessels. These preparations showed that the course of the tonsillar lymph is fairly constant. The vessels pass from the external portion of the tonsil through the peritonsillar connective tissue, the pharyngeal aponeurosis, and the superior constrictor of the pharynx, and as two or more fine vessels, run obliquely downward, backward, and outward, passing below the facial artery, between the internal jugular vein and the stylohyoid muscle, to the superior surface of a large gland, just beneath the anterial border of the sternomastoid. The efferent vessels of this gland are generally two, passing into the internal jugular group of glands, and the jugular lymph trunk. In none of the preparations did the fluid pass into any of the superficial glands. The gland affected in tonsillitis is external and slightly anterior to the internal jugular vein. Enlargement dislocates it outward and forward, so that it appears to be superficial. Enlargement of the submaxillary glands from carious teeth is found along the edge of the jaw, and cannot be displaced backward or downward.

**Certain Hypertensive Crises in Arteriosclerotic Subjects.**—John Bradford Briggs eliminates all cases of general arteriosclerosis, all gross cardiac lesions, and manifest interstitial nephritis, and finds outside of these a group of patients presenting various symptoms, but only the physical sign of high tension pulse. They are all near or have passed the climacteric; whether their years be many or few, they are all physically old. The high tension is the sign of physiological old age. One of the important symptoms may be a permanent trace of albumin in the urine, with a few tube casts. There is an intimate relation between pathological states of high blood pressure and renal permeability to albumin. If hypertension is not the inevitable forerunner of albuminuria, it is its constant companion. In most patients whose albuminuria is a cause for anxiety, the rise of blood pressure is an early danger signal. Entirely aside from transient febrile and cyclical albuminurias, there are cases in which we can detect traces of albumin in the prenephritic stage, when irreparable kidney changes have not as yet taken place. Such a sign is of value in suggesting treatment for the patient which shall prevent the onset of nephritis. These cases have nervous symptoms, such as headache, clonic spasms, stupor, and irregular respiration, combined with high blood pressure. There will be a trace of albumin and a few casts, with low specific gravity. Another type has diarrhea, and slight vertigo, with the same urinary and blood symptoms. There may be peculiar sensations in the hands, with clonic spasm of one extremity. The treatment for all these cases consists of remedies to favor elimination and reduce blood pressure. The author gives the following conclusions: (1) Albuminuria in the subjects of generalized arteriosclerosis, when there is no other cause, is always accompanied by high blood pressure. (2) Intermittent attacks of hypertension of the pulse and albuminuria, separated by longer or shorter intervals, may be the only clinical expression of a generalized arteriosclerosis. (3) Therapeutic treatment for such hypertension, if not carried too far, will relieve the pathological condition of the urine. In some cases we may hope to postpone the onset of chronic renal changes.

**Tinea Versicolor in an Institution.**—Henry J. Nichols takes up the history of tinea versicolor, which has been mistaken for various other discolorations on the skin. There is still uncertainty as to the classification of the parasite and the means of cultivation. From a clinical standpoint, in regard to the predisposing causes of the infection, the question of contagion, and the age limits there is difference of poinion. It has come to be generally recognized that the disease is the result of a microorganism. The parasite is the microsporon furfur; spores and threads have been found in scrapings from the skin. Inoculation has been accomplished, but the questions of classification and culture are still unanswered. It is still doubtful whether a pure culture has been obtained. The author observed forty-two cases out of a population of 700 men, in an institution, in 1904, and gives us the results of his observations. Of the entire number 5.92 per cent. were infected. The disease has been found by different observers to be fairly frequent: 1.6 to 6.25 per cent., and among prostitutes, in Hamburg, as high as 20 per cent. Civilians, who are in large part segregated, are infected to a greater degree than soldiers. The largest number of cases are among old persons; average age was forty-seven. It is found in the sternal hair of old men, as coarse white or yellowish scales. Microscopical examination shows spores, but not mycelia. The spores lie in almost solid sheets. It is probable that in old cultures, as in old age, a resting stage is reached. Organic disease, such as consumption, does not seem to be a cause. The disease is fairly frequent among the chronic insane. Attempts at cultivation isolated a fungus which liquified gelatin and showed other so-called characteristics of the germ; but its variable morphological properties have made any conclusions impossible. Sulphurous acid proved most rapid and effective in its action to destroy the parasite. Sodium hyposulphite was applied to the scales, and then tartaric acid added, developing the sulphurous acid.

**The Negative Value of Kernig's Sign.**—Robert N. Wilson discusses the flexion-contracture symptom, known as Kernig's sign, in meningitis, with a view to prove its negative value. The sign is usually, though not invariably, present in undoubted cases of meningitis. This sign may not appear until late in the disease, may be unilateral, and may be transient or entirely absent throughout the disease. Kernig's sign was observed in three cases of pneumococcus meningitis throughout the disease, and continuing after complete recovery. Two intelligent patients stated that it was present before the illness. The author studied the patients in the medical wards of the Philadelphia Hospital, who showed no symptoms of meningitis. He believes that most healthy persons are unable to avoid a slight angle of flexion when this test is made. He examined one hundred and twenty cases, seventy-three adults, and forty-seven children under ten years of age. In the adults Kernig's sign was present in twenty-nine cases; in children, in three cases. Of the total number, the sign was present in thirty-two cases, in the absence of any clinical signs of meningitis. None of these had Argyll-Robertson pupils. Patellar reflexes were absent in seventeen cases without evidences of nervous disease. The anthor believes that Kernig's sign is an exaggeration of the normal tendency to contract on the part of the flexor tendons, due to irritation or disease of the brain. We must conclude that Kernig's sign is by no means a positive indication of meningeal, or brain, or cord disease, but that when present with other signs of meningitis, it is confirmatory in a high degree. It persists

into convalescence, and is one of the last signs to disappear.

**Diminutive Spleen.**—W. J. Calvert reports a case of a Filipino woman who came to autopsy for leprosy. The spleen was found to be very small, and incased in a mass of fat. It was 32 millimeters long and 10 wide, with 9 millimeters of thickness, and weighed 2 1-10 grains. The color was deep, the capsule smooth, and the blood-vessels degenerated. The arteries were found to be thickened, and their endotheleine degenerated, with deposits of lime. The pulp was much diminished, and only one Malpighian corpuscle was observed, which was mainly composed of connective tissue. It in no way suggested any inflammatory process. Rudimentary development of the spleen is frequent. Twelve cases of absent spleen have been reported. The condition of spleen in the author's case would indicate arrest of development early in embryonic life. In cases of this kind the space that would be occupied by the spleen is filled by a mass of fat. This is irregular, not the shape of the spleen. The posterior border is further from the vertebral column than normal; the relative splenic dullness in the lower border of the lung is absent or moved anteriorly. The size and shape of the fat mass is fairly constant. These are all the points present to aid in the diagnosis of absent or small spleen.

**Torsion of the Great Omentum.**—H. Irving Pinches and Edred M. Corner have devoted some time to the consideration of torsion of the omentum, which is fairly frequent. Torsion of the bowel in strangulated, obstructed, or painful and irreducible hernia is far from uncommon. It is removed after the reduction of the hernia by the pressure of the gas in the intestine. The testes and cord are also frequently twisted in the hernia, and we may expect that the omentum has undergone a similar process. All cases recorded, up to the end of 1904, have been collected, and four new ones are published, making the number fifty-three in all. The cases fall into three groups: abdominal, six examples, hernial, the torsion occurring solely within the sac, six cases; hernial and abdominal, forty-one cases. The condition is more frequent in males and in middle life. A hernia was present in 90 per cent. of the cases, but in none was there femoral hernia. Previous crises, or attacks of pain in these cases are of importance, and are probably due to increase of the tension, as ten or more twists have been found. The clinical symptoms are pain in the abdomen, and in some cases in the hernia itself. In eleven cases it was at McBurney's point. Vomiting is not a constant symptom. The bowels may be inactive, or diarrhea may be present, or flatus only passed. The pulse is accelerated, the temperature slightly raised. A tumor may generally be felt, both in the hernia and in the abdomen. All of the patients, except eight, recovered; hence the prognosis is good. Instances of abdominal torsion, without any hernia, are 10 to 12 per cent. of all cases of omental torsion. The condition requires immediate operation. Torsion accompanied by a hernia shows all the symptoms of a hernia, which is usually irreducible, incarcerated, or strangulated, and demands operation. In some cases the hernia has been reduced without relief to the symptoms.

*Annals of Surgery, August,* 1905.

**Final Results in the X-Ray Treatment of Cancer, Including Sarcoma.**—Since February, 1902, William B. Coley has made an earnest endeavor to determine the value of the *x*-ray in the treatment of malignant tumors, and he arrives at the following conclusions: (1) That the *x*-ray exerts a powerful influence upon cancer cells of all varieties, but most marked in cases of cutaneous cancer. (2) In some cases, chiefly in superficial epithelioma, the entire tumor may disappear, probably by reason of fatty degeneration of the tumor cells with subsequent absorption. (3) In a much smaller number of cases of deep-seated tumors, chiefly cancer of the breast and glandular sarcoma, tumors have disappeared under prolonged *x*-ray treatment. In nearly every one of these cases, however, that has been carefully traced to final result, there has been a local or general return of the disease within a few months to two years. (4) In view of this practically constant tendency to early recurrence, furthermore, in the absence of any reported cases well beyond three years, the method should never be used except in inoperable cases, or as a prophylactic after operation, as a possible, though not yet proven, means of avoiding recurrence. (5) The use of the *x*-ray as a preoperative measure in other than cutaneous cancer is contraindicated. (*a*) because the agent has not yet been proven to be curative; (*b*) because of serious risks of an extension of the disease to inaccessible glands or to other regions by metastases during the period required for a trial of the *x*-ray.

**Hypertrophic Pyloric Stenosis in the Infant.**—The following case reported by J. M'Gregor Robertson affords material for a critical consideration of points of significance in the evolution of the clinical history of pyloric stenosis in infants. A plump, healthy looking male was nursed by the mother, and for the first six weeks thrived exceedingly, when he began to put up a little now and again after a drink. The vomit was suddenly projected *en masse* with force, and day after day this tendency to put up, after a drink, a portion or all of the meal increased. There was a suggestion of three nerve phenomena: (1) A sluggishness of pupils; (2) a faint rigidity of the muscles of the neck; (3) a tendency to turn the eyes downward. These symptoms later became quite distinct. From the sixteenth day of illness to the thirtieth day the chief facts had been, (1) the vomiting of more or less food, sometimes little, sometimes much, occurring from one to three or four times in the twenty-four hours, always with much explosive force; (2) the erratic temperature; (3) elusive suggestions of nerve symptoms. The rectum was very irritable, as well as the pharynx. The first and only time that gastric peristalsis was visible was on the thirtieth day. On the thirty-third day he first detected on palpation a thickening in the region of the pylorus, and an operation was advised and consented to, the child bearing the operation well, but dying fourteen hours later. The whole gastric wall was found to be uniformly hypertrophied, though dilatation was not marked, and the extreme pyloric thickening made clear the nature of the disease. A gastroenterostomy was performed with great difficulty, the duodenal wall being extremely thin and the lumen small. When a glass tube was tied into the cardiac end and the stomach filled with water, there was not a single leak at the pylorus. There was an extremely narrow channel through the pylorus left patent by the hypertrophy, and this was occluded by the rugæ and the dense secretion.

**Combined Volvulus and Hernia Through a Recent Mesenteric Slit.**—This case with a resection of five and one-half feet of intestine, death occurring on the ninth day, is reported by H. C. Curl, and was of special interest because of the comparatively slight reaction on the first day, and the unusual combination of a volvulus and a large mass of intestine strangulated through a mesenteric rent, evidently of recent origin, and occurring without a history of any strain or trauma to cause it.

**Punctured Wounds of the Bladder.**—A report of one case, with a review of the literature, is presented by Edward Evans and Harry Atwood Fowler. Statistics were given which served to emphasize two points, that wounds of the bladder were extremely uncommon, and that they occurred most frequently in the experience of military surgeons. The case reported occurred in the practice of Dr. Evans and presented the following interesting features: (1) The circumstances surrounding the injury were most fortunate, allowing immediate laparotomy and suture of the intraperitoneal wound of the bladder. (2) The wound of the perineum, rectum, and trigone was so extensive as to necessitate surgical interference for the restoration of function. So far as they were able to discover this was the only case on record requiring an operation for the repair and closure of a perineal wound of the bladder. (3) The restoration of function was complete despite the severe injury to the trigone and to the seminal vesicles and ducts.

**Dislocation Forward of the Atlas, with Fracture of the Odontoid Process of the Axis.**—This case is reported by James A. Kelly, *x*-ray photographs are shown, and the following conclusions are drawn: The diagnosis of dislocation forward of the atlas upon the axis with fracture of the odontoid process of the latter is based upon the following: (1) The history of injury and the clinical symptoms demonstrated the conditions. (2) The *x*-ray photograph demonstrated the dislocation. (3) The absence of pressure symptoms proves conclusively that a fracture of the odontoid process must have been present in combination with the dislocation. (4) The anatomical preparations show that pressure upon the cord would have occurred unless the odontoid process had been fracture.

**Fracture of the Carpal Scaphoid.**—This injury, formerly thought to be very rare, is reported by Leonard W. Ely. Since the introduction of röntgenography it has been found to be of fairly frequent occurrence.

**Transmesenteric Hernia of the Appendix Vermiformis.**—This case is reported by Alfred C. Wood. Although some of the features were unusual, the condition was thought to be appendicitis, with an abscess. The peritoneal cavity was opened by an incision over the mass which occupied the normal position of the ascending colon and had the general shape and size of this structure. It was firm to the touch and had a very deep red color. At three or four points areas of softening were seen, suggesting the breaking down of the mass. The mass was thought to be colon, altered by inflammatory action and lymph formation. As the appendix could not be found, it was supposed to be in this mass, but a careful search failed to disclose a trace of it. The areas of softening were found to be suppurating,

epiploic appendages. When the survey was extended the cecum was recognized firmly fixed in position. The longitudinal bands could be seen. The anterior band led backward and upward, and seemed to be lost beneath the mesentery. On inspecting the opposite surface of the latter, after displacing a portion of adherent omentum, a small, rounded structure was seen projecting from it. The condition at once became clear; the appendix had slipped through a hole in the mesentery and had become strangulated. It was reduced with some difficulty; as soon as the appendix was liberated the unusual fixation of the cecum was relieved. The illustration shows the appendix to be strangulated at its base, the organ having doubled upon itself and slipped into a hole in the mesentery. It had ruptured at the point of constriction. The mesoappendix was unusually large and fleshy.

*French and Italian Journals.*

**Survival After Interscapulothoracic Amputation for Malignant Tumors.**—E. Jeanbrau and V. Riche have collected 125 cases of interscapulo-thoracic amputation of the upper extremity, from various operators, with a view to ascertain the mortality and the length of survival after this operation in cases of malignant tumor. These cases were collected from the personal records furnished by surgeons of good standing of all countries, so that the statistics obtained are of much more value than ordinary hospital statistics. The author gives us these conclusions: The mortality of the operation is 7.84 per cent. since 1887, against 26.16 per cent. previous to the introduction of the technique of Berger-Farabeuf. If we do not take into account the cases in which outside causes operated to produce death, the mortality has fallen to 5 per cent. The average life of patients after operation has been three years. This is an excellent result when we consider that the patient accepts this serious operation only when he has reached a very advanced stage of disease, and when the general health has become very much impaired. Cure is possible, since there are found twenty-four cases of cure in the last five years. Among these are patients who have lived thirteen, fifteen, and twenty-six years after operation.—*Revue de Chirurgie*, August, 1905.

**Inflammatory Tuberculosis.**—Ch. Vinay considers many of the manifestations of tuberculosis as inflammatory in their nature. The bacilli do not themselves become localized and produce tubercle, but the life-products act as poison in the tissues and cause localized inflammations. The virulence of the organisms seems to become attenuated by the resistance of the patient, or the quantity of toxin is less. The action of the bacillus is arrested by the reactionary phenomena of the patient. These lesions cannot be differentiated from similar processes produced by other infectious agents by their anatomical characteristics. Only their etiology is specific. These lesions are congestive, exudative, or serous at the beginning; later they become sclerotic, and after a long time cicatricial. There may be all stages for a slight congestion to an ankylosis of the joints, or a progressive cirrhosis. These processes attack all sorts of tissues: they include lesions of the articulations, tendinous serous membranes, peritoneum, pleura, pericardium, vessels, nervous system, skin, ears, and ocular structures. There is neither formation of milliary tubercles, nor caseation. The digestive tube is attacked in this way, hypertrophy and ulceration being produced, and stenosis following. In the nervous system we have peripheral nervous troubles, myelitis, and meningoencephalitis. We have arteriosclerosis and interstitial nephritis, and cirrhosis of the liver. The prognosis in these lesions is less grave for life than in the granular infection. Treatment is general, but altitude is of less value than in pulmonary tuberculosis.—*Revue de Médecine*, August 10, 1905.

**Defense of the Parasitic Theory of Cancer.**—L. Bertrand has collected various facts in support of the parasitic theory of cancer, some of which are the result of very recent experiments on animals. Jensen has caused the transmission of cancer from one mouse to another in twenty-three cases, and this has succeeded only when the cells transmitted from one animal have been perfect and living. He tried to inoculate a rabbit with cancer from a mouse. In this he did not succeed, but he developed in the serum of the rabbit an antitoxic substance, which when injected into the mouse caused the disappearance of cancer. He thus demonstrated incontestably the existence of a cancerous toxin. The proliferation of cancer epithelium is not an exceptional occurrence. In one cage of mice where cancer existed, Borral found twenty other cases occurring within two years. There had been no outside source of infection. In cages of mice where there were no cases of cancer generations of hundreds of mice have been raised without the occurrence of one case of cancer, and cancer does not occur among wild mice at all. This cancer among mice is a true epithelioma, which starts from the glandular culs-de-sac, and appears on the border of the tube, anus, and in the axilla, or abdomen. Metastases occurring are always intravascular, or intravenous. Haarland inoculated animals with a cancerous virus which had been filtered through a Berkfeld filter. He succeeded in producing an adenocarcinoma of the mammary gland. He did not succeed in other cases because all the mice died. This seems to show that the virus was in the filtered material.—*Société Médico-Chirurgicale d'Anvers*, June-July, 1905.

**Diagnostic, Prognostic, and Therapeutic Value of Lumbar Puncture in the New-Born.**—Louis Devraigne believes that lumbar puncture can be of great use to the accoucheur as a means of diagnosis, and from the standpoint of prognosis and treatment in cases of submeningeal hemorrhage in newborn children. Whenever this hemorrhage is beneath the membranes it establishes the diagnosis if puncture is made before the child is moribund, and after the cerebrospinal fluid has had time to become tinged with the blood of the hemorrhage. If the hemorrhage is between the membranes and the skull the fluid will remain clear. In true intradural hemorrhage there will be convulsions, cyanosis, and coma, contractures, and rise of temperature. Soon after the puncture the condition of the child should improve, and the prognosis will become less grave. After one or two punctures the child may recover entirely. The operation is very easy in the new-born. It is absolutely without danger.—*La Presse Médicale*, August 16, 1905.

**Etiology of Putrid Pleurisy in Children.**—Gaetano Melli made careful bacteriological examinations of the exudate in two cases of empyema in which there was an odor of decomposition to the discharge, in order to ascertain what bacteria were present. The germs that are generally found in such cases are the pneumococcus, staphylococcus, tetragonus, bacillus coli, proteus vulgaris, leptothrix, bacillus of diphtheria, etc. One of his cases was secondary to typhoid fever. In this case there were present in the exudate the streptococcus and the bacillus of Eberth, and the bacillus fusiformis of Vincent. This is the first time that the bacillus of typhoid has been reported in empyema. In this case it was found in large numbers in the gangrenous foci and in the tissue about them. It was demonstrated to be virulent to animals. This germ when associated with the streptococcus acquires added virulence. In the second case also he found the streptococcus associated with the bacillus fusiformis of Vincent. This microorganism is found habitually in gangrenous foci of ulceration of the mouth, and it is now thought to be specific in this disease. Putrid pleurisy is usually associated with gangrenous foci in the lungs, which was the case in these two examples, one from the pneumonitis of typhoid, the other from an infection with the spillum of Vincent from an ulceration in the mouth.—*Rivista di Clinica Pediatrica*, August, 1905.

**The Effect of Endovenous Injections of Sublimate in Puerperal Infections.**—Pende has used this treatment with some success in several severe cases of puerperal infection. Eliminating cases that yield easily to intrauterine douches and aseptic treatment, and those in which there is a secondary localization of the poison with pelvic peritonitis, inflammation of the adnexa, and phlebitis, he selected cases of true puerperal septicemia, in which for several days there had been general symptoms not modified by disinfection of the uterus. He gave for three successive days an injection daily of 2 to 3 milligrammes of corrosive sublimate. The fever fell rapidly and in a truly marvelous way the patient entered on a permanent apyrexia. The author thinks these results so encouraging that this method of treatment should be used sufficiently to test its efficiency thoroughly.—*La Riforma Medica*, August 12, 1905.

**Effect of Röntgen Rays on Non-Suppurative Tuberculous Adenitis.**—I. Valobra has treated three cases of non-suppurative adenitis by the Röntgen-ray, using a hard tube, at a distance of 30-40 centimeters from the region to be treated, protecting the surrounding skin by an aluminum shield. He found that after each sitting there was a marked reaction, characterized by fever, swelling of the affected glands, and general symptoms, lasting some days. These symptoms were immediately followed by a rapid absorption and decrease in the size of the glands. The result of ten to twenty treatments was a marked decrease in the size of the glands, and reduction of the deformity caused by them. In *x* ray treatments the skin reactions do not appear until some time after the applications, but in treatment for cancer of the internal organs, and for leukemia, these phenomena of severe reaction are observed, accompanied by rapid diminution in the size of the growth. The author questions whether such action will be followed by a generalization of the tuberculous infection. Sufficient time has not elapsed to decide this question. The Röntgen-ray in bearable strength does not kill the bacilli of Koch. The author thinks that in undoubtedly tuberculous glands it is well to avoid a violent reaction, giving short sittings, and mild treatment, so as to avoid the chance of causing generalization of the infection.—*Giornale della Regia Accademia di Medicina di Torino*, Vol. XI, 5 and 6.

# Book Reviews.

Diseases of the Skin. Their Description, Pathology, Diagnosis, and Treatment, with Special Reference to the Skin Eruptions of Children, and an Analysis of Fifteen Thousand Cases of Skin Disease. By H. Radcliffe-Crocker, M.D. (Lond.), F.R.C.P., Physician for Diseases of the Skin in University College Hospital; Honorary Member of the American Dermatological Society; Membre Correspondant Etranger de la Société Française de Dermatologie; Correspondierendes Mitglied der Berliner dermatologischen Gesellschaft; Socio Onorario della Società Italiana de Dermatologia e Sifilografia; Late Physician to the East London Hospital for Children; Examiner in Medicine, Apothecaries' Hall, London. Third edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co., 1905.

This third edition of Radcliffe-Crocker's classical treatise on dermatology is announced as a special illustrated edition, this designation being based upon the presence of one hundred and twelve illustrations in the text and seventy-six well-executed inset plates. This edition differs quite materially from the preceding in some respects, though the body of the work, dealing with affections of common occurrence and definite history, in which changes of doctrine are slow and slight, remains practically the same. Among the most important additions are chapters or sections on x-ray dermatitis, bronzed diabetes, erysipeloid, sarcoid, blastomycosis, Veld sore, Mortimer's malady, and antitoxic serum eruptions. Some of the articles have been rewritten and to others more or less extensive additions have been made. This illustrated edition is in two volumes containing nearly fifteen hundred pages, and constitutes in its present form one of the best works on diseases of the skin in our language.

Medical Philology. Gathered by L. M. Griffiths, M.R.C.S., Eng. Part I, A.-El. Bristol, England: J. W. Arrowsmith, 1905.

This is a reprint of the interesting medicophilological notes which used to appear from time to time during a period of about ten years in the *Bristol Medico-Chirurgical Journal*. Unfortunately the contributions were brief and appeared only at intervals of several months, and consequently the notes include only the early part of the alphabet, ending with "Elfe." The foundation of the collection consists of the words possessing a medical significance found in the "Promptorium Parvulorum" and "Catholicon Anglicum," two English-Latin dictionaries dating from the fifteenth century or earlier. Dr. Griffiths quotes freely from the annotations of Way and Herrage and adds numerous interesting comments of his own, and cites instances of the uses of the words by Shakespeare and others. We hope he will be able to complete the work on the lines followed in this fragment.

Psychological Medicine. A Manual on Mental Diseases for Practitioners and Students. By Maurice Craig, M.A., M.D., Cantab, M.R.C.P., Lond., Physician for and Lecturer on Mental Diseases, Guy's Hospital; Clinical Teacher of Psychological Medicine, Royal Army Medical College, London; Senior Assistant Physician, Bethlem Royal Hospital, London. Philadelphia: P. Blakiston's Sons & Co., 1905.

In this work the author addresses especially the general practitioner and the student of medicine, rather than the professional alienist, and the book throughout bears evidence that the thought of such an audience was ever present with him. He endeavors in every way repeatedly to impress upon his readers the very real fact, which tradition and superstition even now often obscure, that the term, "mental disease," has the accent on the second word; in other words, that the insane are not possessed of the devil or inspired by the Lord, but are simply and solely ill, just as ill as if their malady were tabes dorsalis or pulmonary tuberculosis.

The work begins with a short chapter on normal psychology in which the non-specialist is put in possession of the essential facts of normal mental processes, as necessary for the student of mental disease as a knowledge of physiology is for the student of diseases of the body. A chapter is devoted to sleeplessness, this distressing condition being so prominent a symptom in, and especially so often a cause of psychic disturbance. There is also a chapter on the legal relation of insanity, but as this has to do necessarily with English law solely, it is not so useful to American readers as the other portions of the work. Dr. Craig possesses the faculty of clear expression in simple language, his work is free from useless verbiage, and he avoids the use of newly coined words and of those with newly specialized meanings to which writers on psychology, normal or pathological, seem to be particularly given. The work is one that can be commended.

Psychiatry. A Textbook for Students and Physicians. By Stewart Paton, M.D., Associate in Psychiatry, the Johns Hopkins University, Baltimore; Director of the Laboratory, the Sheppard and Enoch Pratt Hospital, Towson, Maryland. Philadelphia and London: J. B. Lippincott Co., 1905.

The author of this work insists upon the recognition of the fact that insanity is but a symptom of disease, that anomalies in thought, action, volition, and emotion are merely "the expression of a disordered functioning of the central nervous system," and the chief duty of the psychiatrist is to prevent the conditions which lead to this abnormal functioning. The study of alienation is a branch of general medicine, and the diagnosis and early treatment of mental disorders lie, or should lie, within the province of the general practitioner who, of necessity, sees the patient and treats him before the alienist is consulted. It is at this time, as is the case in all disease, that treatment is most effectual; in the case of mental disorders, indeed, it is practically the only time when treatment offers much hope of success.

The causes of insanity, its nature, its general symptoms, and the broad principles of treatment are discussed in separate chapters, as well as in the section treating of individual forms of alienation. In the other chapters are discussed the psychoses resulting from automtoxication, from chronic intoxication, or from imperfect functioning of the thyroid gland, and those associated with organic disease of the central nervous system; the diseases embraced in various groups—the manic-depressive, the dementia-præcox, the dementia-paralytica, the epilepsy, the hysteria, the paranoiac, and the senile; the neurasthenic and psychasthenic states; and mental anomalies due to defective development of the central nervous system. The book is well illustrated, as regards quality rather than quantity; there are twenty excellent plates and a number of illustrations (specimens of handwriting, temperature charts, etc.), in the text.

Dr. Paton has given us a very useful book and one that cannot fail to be of service to the general practitioner and student. Its object is largely the prevention of insanity and the bettering of the brain power of the race—a betterment which will be needed more and more as the world advances in civilization.

Health and Disease in Relation to Marriage and the Married State. A Manual contributed to by Drs. G. Abelsdorf, L. Blumreich, R. Eberstadt, A. Eulenburg, C. A. Ewald, P. Fürbringer, M. Gruber, W. Havelburg, A. Hoffa, R. Kossmann, F. Kraus, R. Ledekman, A. Leppmann, E. v. Leyden, E. Mendel, A. Moll, A. Neiser, J. Orth, S. Placzek, C. Posner, P. F. Richter, H. Rosin, W. Wolff. Edited by Prof. Dr. H. Senator and Dr. S. Kaminer. The only authorized Translation from the German into the English language, by J. Dulberg, M.D., of Manchester, England. Vol. II. New York: Rebman Company; London, Rebman, Ltd., 1905.

The first half of this work appeared about a year ago and was noticed in the Medical Record of December 10, 1904. The present volume completes the work, and consists of chapters on Gonorrheal Diseases in Relation to Marriage; Syphilis in Relation to Marriage; Diseases of the Skin in Relation to Marriage; Diseases of the Organs of Locomotion; Diseases of the Eyes, with Especial Regard to Heredity; Diseases of the Lower Urogenital Organs, and Physical Impotence; Diseases of Women, including Sterility; Diseases of the Nervous System; Insanity in Relation to Marriage; Perverse Sexual Sensations and Psychical Impotence; Alcoholism and Morphinism in Relation to Marriage; Occupational Injuries in Relation to Marriage; Medico-Professional Secrecy in Relation to Marriage; The Economic Importance of Sanitary Conditions. In both of these volumes there is an entire absence of histories; and the completed work is an encyclopedia of all that appertains to medicine and marriage. The work is intended for the general practitioner, and the reader will find here all the information that he can possibly want on the subject. The work includes a bibliography, essentially German, and an index.

Handbook of Anatomy. Being a Complete Compend of Anatomy, Including the Anatomy of the Viscera and Numerous Tables. By James K. Young, M.D., Professor of Orthopedic Surgery, Philadelphia Polyclinic; Clinical Professor of Orthopedic Surgery, Woman's Medical College of Pennsylvania; Instructor in Orthopedic Surgery, University of Pennsylvania; Fellow of the College of Physicians of Philadelphia; Fellow of the Philadelphia Academy of Surgery; Fellow of the American Orthopedic Association; Member of the American Medical Association, etc. Second edition, revised and enlarged. Philadelphia: F. A. Davis Company, 1905.

This is the most recent anatomy compend on the market; it is larger than most of its competitors, but otherwise does not differ from them in any notable feature.

# Society Reports.

## AMERICAN PROCTOLOGIC SOCIETY.

*Seventh Annual Meeting, Held in Pittsburg, May 5 and 6. 1905.*

THE PRESIDENT, DR. J. R. PENNINGTON OF CHICAGO, IN THE CHAIR.

**President's Address.**—Dr. J. R. PENNINGTON, in this address, referred to the adverse criticism which the organization and continued prosperity of this Society had provoked in certain quarters. He then proceeded to show that its existence was a logical and necessary step of progress. Special societies arise by a process of natural differentiation. This differentiation, which is unavoidable, by organization of the resulting groups makes possible a greater definiteness of structure and function of the medical profession. Special organizations had multiplied more rapidly in the past thirty years than during any previous period, and likewise the advancement in the science of medicine had been greater during the same period. But the subject of proctology had been neglected in the past until the charlatan claimed it as his special field and the profession seemed still be doing its utmost to support the claim. Of the sixty-six institutions belonging to the Association of American Medical Colleges only eight made any provision for teaching proctology. The Association had adopted a uniform curriculum consisting of twenty-seven subjects. This extensive course provided for thirty hours to be given each to medical jurisprudence, dietetics, hygiene, and public health, sixty hours each to nose and throat, and genito-urinary diseases, and 160 hours to gynecology. No reference whatever was made to the subject of rectal diseases. "In view of the fact that the greatest breach in the science of medicine to-day is, and always has been, at this very point," he said, "and that it is proverbially true that because of this breach the charlatan is more securely intrenched in this than in any of the other departments, I fail to see the equity in such a curriculum. It may be claimed by the Association of Colleges and by those schools that do not include proctology in their curricula, that the chairs of general surgery devote a certain number of hours to these diseases. If so, why are there so many physicians in this country who have never heard a lecture on rectal diseases nor witnessed an anorectal examination or operation?" The speaker concluded that there was a distinct work for this Society, viz., the reclamation of this specialty for ethical medicine, and that the Society would exist, prosper, and grow in influence in proportion as it met this need.

**Malignant Disease of the Rectum and Its Treatment.**—Dr. G. B. EVANS of Dayton, O., read this paper. He prefaced his remarks with a plea for thorough examination of all patients complaining of rectal symptoms. Many cases of uterine cancer had been termed "change of life," and very many cases of rectal cancer "piles," because of neglect of this precaution. It was the consensus of opinion that cancer was at first purely local and that early recognition and thorough extirpation would cure a large proportion of all cases. Formerly the author was an advocate of colostomy in these cases, but now believed that this procedure should be reserved for those cases only which had advanced so far as to render the radical operation hopeless. The only contraindication he would recognize as absolute was fixation of the rectum by extension of the growth to adjacent structures. The perineal and combined abdominal and perineal routes were recommended.

**The Ambulant Treatment of Internal Hemorrhoids.**—Dr. C. F. MARTIN of Philadelphia presented a paper on this subject, in which he strongly defended the injection method. His technique consisted in the injection of 7 to 10 minims of a 50 per cent. solution of phenol into each pile tumor at intervals of from two to seven days, depending on the effect produced. As a preliminary to beginning the injection the author recommended divulsion of the sphincters under nitrous oxide anesthesia, much of his success with the method being attributed to this procedure. He concluded that there were not more than 15 per cent. of recurrences and that accidents and complications were by no means so frequent as after the ligature and clamp and cautery operations. In addition the method was practically painless and the patient was not detained from business.

**Cases of Fecal Impaction of the Rectum.**—Dr. T. C. MARTIN of Cleveland, O., reported these cases. After giving the symptoms usually complained of by these patients, he emphasized the value of the proctoscope in treatment as well as diagnosis. One of the cases reported was of special interest in that the cause was found to have been a ventral fixation of the uterus in which the rectum, by means of the uterosacral ligaments, had been anchored so immovably that the patient could no longer bear down effectually.

**Urethrorectal Fistula.**—Dr. W. M. BEACH of Pittsburg, Pa., read a paper with this title. After citing a number of cases and describing his method of treatment the author drew the following conclusions: (1) Urethrorectal fistula is comparatively rare and very easily overlooked. When in doubt, use the permanganate test. (2) It generally follows prostatic abscess of gonorrheal origin. (3) It may result from traumatism—faulty use of sound, lithotomy, etc. (4) This is one type of fistula which demands suturing. The suture material should be No. 3 forty-day catgut. (5) The care of the wound should never be left to an assistant; no one can possibly know as much about it as he who made it. (6) A certain number of cases of recent urethral origin will heal spontaneously when the stricture is relieved.

**Pruritus Ani.**—Dr. LEWIS H. ADLER of Philadelphia presented a paper entitled "A Further Contribution to the Study of Pruritus Ani, with Special Reference to Its Local Treatment." In the author's experience the male sex had been affected in about 95 per cent. of cases. In nearly all the cases the patients were more or less neurotic, and in the major portion, of a decidedly bilious temperament. These cases demanded the removal of all exciting causes, and regulation of the patient's habits of life should precede and attend local treatment. The latter consisted in the daily injection into the cavity of the rectum of from 1 to 2½ drachms of a mixture of fluid extract of hamamelis, 1 fluid ounce; fluid extracts of ergot and hydrastic and compound tincture of benzoin, each 2 drachms. Upon the first visit if the perianal skin was dry and tough the entire surface should be painted with a concentrated solution of silver nitrate (960 grains to the ounce). This might require repetition several times at intervals of a few days to restore the skin to its normal condition. After this was accomplished citrine ointment in full strength was to be applied and renewed daily for the first two or three weeks, and thereafter on alternate days or twice a week. This method of treatment might extend over a period of six months or even longer, but in the author's hands it had proved uniformly successful.

**The Operative Treatment of Tuberculous Rectal Fistula in the Tuberculous.**—Dr. J. COLES BRICK of Philadelphia presented this communication. The frequent association of rectal fistula and phthisis had long been recognized. Some authors claimed that 5 per cent. of consumptives developed fistula, and Hartman found that of forty-eight patients with fistula twenty-three were positively tuberculous. In the author's opinion the irritating effects of the other were often responsible for the onset of pulmonary symptoms. For this reason he employed nitrous oxide and oxygen when a general anesthetic was demanded. All raw surfaces were seared with the hot iron. When the case was extensive it was better to perform the operation in stages, so as to minimize the period of confinement to bed. Special stress was laid on the after management of these cases. The patient should be kept in bed as little time as possible, but no active exercise allowed until weight had returned to normal. Forced feeding and out-door air were recommended, and daily sponging with tepid water, or if the

patient's vitality was sufficient, with cold water, was of great value. A weekly gain of weight was the one standard of favorable progress. In conclusion the author advised that all fistula patients be carefully examined for local and pulmonary tuberculosis, and, even though the examinations were negative, that every case be treated as though tuberculosis were likely to be developed.

**Personal Experience in the Employment of Mechanical Vibration in the Treatment of Rectal Diseases.**—Dr. W. L. Dickinson of Saginaw, Mich., read this paper, in which he concluded that this was a valuable method of treatment and deserving of more general use by the proctologist. A number of instances were recounted in which it had been successfully used for the relief of fissure and to accomplish dilatation of the sphincters. But the author thought that its greatest field of usefulness was in the treatment of chronic constipation, and gave the technique of its application in such cases.

**The Office Treatment of Rectal Diseases and Its Limitations.**—Dr. Jas. P. Tuttle of New York read this paper. He said that the trend of practice in rectal diseases at the present day was threefold: (1) Toward a more general resort to operative measures; (2) toward a wider application of local anesthesia; and (3) toward a great increase in office treatment. These tendencies were due to the following facts: First, the public as well as the profession had learned that nonoperative measures could not be relied upon for permanent cures. Second, dread of general anesthesia had greatly diminished, due chiefly to improved methods in the use of ethyl chloride and nitrous oxide, alone or as adjuvants to ether. Third, dissemination of the knowledge that most of the minor rectal operations can be done under cocaine or other local anesthetic with as little pain and almost as little detention from business as was occasioned by the nonoperative measures which gave only temporary and uncertain relief. Fourth, local anesthesia was being more generally adopted because it was safer, could be more quickly applied, simplified the work, and at the same time, if properly used, permitted of as thorough work as general anesthesia. A 1 per cent. solution of cocaine, eucaine, or stovaine was as strong as it was ever necessary to use, and usually ¼ per cent. was sufficient. Stretching of the sphincter had heretofore been the most difficult thing to accomplish under local anesthesia; but the author referred to a method he had devised by which this could be done, thus making it possible to operate painlessly on hemorrhoids, fissures, small fistulæ, ulcerations, tumors low down, and even low strictures. But while these things were possible the author considered certain conditions requisite: (1) Asepsis; (2) careful selection of cases; (3) complicated and plastic operations should not be undertaken; (4) when general anesthesia was necessary it was better to have the patient at home or in the hospital, even though it might be possible to do the work in the office.

**A Contribution to the Pathology of External Piles.**—Dr. Louis J. Krouse of Cincinnati presented this paper. Limiting his remarks to the sanguineous or thrombotic variety, after a review of the literature of the subject and of the anatomy of the parts, the author drew the following conclusions: (1) The walls of the hemorrhoidal veins must undergo some pathological change before a thrombotic hemorrhoid can develop; (2) these changes being present, any undue pressure may cause an aneurysmal dilatation of the veins; (3) when the internal coat of the vessel is altered, there is more tendency for coagulation to occur; (4) sexual activity increases intravenous pressure and thus favors the condition; it is therefore a disease of adult life; (5) the clot is always found in the diseased vessel and never in the perivenous connective tissue.

**A Summary of Twenty-five Radical Operations Upon the Rectum Under Local (Sterile-Water) Anesthesia.**—Dr. A. B. Cooke of Nashville read this communication. The twenty-five operations consisted of: Internal hemorrhoids, 15; prolapsus ani, 2; anal fissure, 2; external hemorrhoids, 6. From this series of cases the author drew the following conclusions: (1) The method is simple, safe, and effective; (2) pain at the time of operation is exceptional; (3) postoperative pain is far less than after the old methods; (4) the time of detention from business is reduced more than half; (5) it offers a reliable means of extending the benefits of surgery to a large class of cases which would otherwise be unsuitable for operation; (6) it robs these operations of their terrors. Summing up his personal experience with the method, the author stated that it had been satisfactory beyond his fondest hopes and, if the promise of the method were realized in future, he would have need for general anesthesia in rectal surgery only in the exceptional case.

Papers by Drs. Wm. Bodenhamer, Leon Straus, and A. Tierlinck, in the absence of the authors were read by title.

**Officers.**—The following officers were elected for the ensuing year: *President,* Dr. Lewis H. Adler, Jr., of Philadelphia; *Vice-President,* Dr. Geo. B. Evans of Dayton, Ohio; *Secretary-Treasurer,* Dr. A. B. Cooke of Nashville; *Executive Council:* Drs. J. R. Pennington of Chicago, Chairman, T. C. Martin of Cleveland, and Wm. M. Beach of Pittsburg.

Time and place of meeting for 1906 to be determined by the Council.

---

## THE BRITISH MEDICAL ASSOCIATION.

*Seventy-third Annual Meeting, Held at Leicester, July 25, 26, 27, and 28, 1905.*

(Special Report to the Medical Record.)

(*Concluded from page 414.*)

### SECTION OF TROPICAL MEDICINE.

*Third Day—Friday, July 28.*

**Tropical Sprue.**—Dr. James Cantlie, Lecturer to the London School of Tropical Medicine, opened the discussion on sprue. He said that there had been no appreciable advance in our knowledge of sprue since the discussion on the subject held five years ago. Many observers had patiently sought for an intestinal organism in the stools of sprue patients, but so far without any positive result. He had lately seen a case of true sprue develop in a man aged sixty, who had lived in England for seven years continuously after leaving China. He thought such a long period of incubation unfavorable to the parasitic theory. He was inclined to regard liability to sprue to arise primarily from a physiological atrophy of certain of the digestive organs due to the prolonged residence in a hot climate. The organ which clinically showed the greatest alteration was the liver. In all sprue patients the liver was markedly reduced in bulk. Owing to the loss of functional activity in the liver, the contents of the bowel were imperfectly digested, numerous organisms developed, and diarrhea followed. The frothy, bulky stools clearly indicated a fermentation, and their pale color pointed to the absence of bile. Stomatitis was very common among adults, especially women, in China; an attack lasted about three weeks, and there might be as many as three or four attacks in a year. Sprue did not necessarily follow upon these attacks, but they preceded the disease, and were a warning that the disease might supervene. He was inclined to ascribe stomatitis to indigestion caused by the use of coarse native oils instead of butter or fat in cooking food. He met with sprue in Europeans only in South China.

In regard to treatment, he condemned the milk treatment. The milk in its passage through the alimentary canal became separated into curd and whey; the whey was absorbed, but the curd was excreted, and gave the apparently solid motion which had neither the appearance nor the smell of feces, and was merely a cheesy mass—fecal cheese, in fact. He advocated the meat treatment of sprue. At first, when the patient was weak, meat juice raw or warmed every five or ten minutes. After a day or so the intervals

of feeding should be increased, and beef jelly, calves'-foot jelly, or plain jelly added. In some four or five days beef (three to five ounces), pounded and lightly cooked, could be given thrice daily in addition to the meat juice and jelly. Tea—China tea—was the best drink; rice tea was also an agreeable and suitable drink; wet packs (warm at first) applied to the abdomen for two hours twice daily were beneficial, accompanied by rest in bed. The meat treatment took as many days to cure the disease as the milk took months. He had lately treated successfully by the meat treatment two patients over sixty years of age. Strawberries (three to four pounds daily), combined with meat, were perhaps more efficient than meat alone. Other fruits would, no douht, be found to take the place of strawberries in the treatment of sprue, but at present none were known No doubt sprue was scorbutic in its nature, and fresh meats, fresh fruits, and fresh vegetables were potent agents in the cure of the disease.

**Hill Diarrhea.**—Dr. ANDREW DUNCAN of London read a paper on this subject. He said that until comparatively recently the disease was held to be one peculiar to the hills, a height of six thousand feet being necessary for its evolution. But it had been reported at Penang Hill, two thousand feet high only, and Dr. Nightingale had reported a case occurring in the plains. As regards the time of its appearance in the hills, it broke out on the onset of the monsoon, ceasing also with the cessation of the rains. The late Surgeon-General Moore of Bombay attributed hill diarrhea to chill. Colonel Crombie held that it was due to some microorganism which invaded the digestive tract, devoured the coloring matter of the bile and perhaps other constituents, and so allowed of rapid fermentative changes in the intestinal contents. But the daily fluctuation of the symptoms, the restriction of the diarrhea and the symptoms to the early morning and forenoon were difficult to explain on this hypothesis, as given the presence of a microorganism as the cause, surely its effects should not be limited to one period of the day. A more satisfactory view, should the facts on which he based his conclusions be verified, was that of Lieutenant-Colonel Dyson, who attributed the disease to the presence of mica in the water. Dyson pointed out that hill diarrhea occurred in those hill resorts where the geological formation contained schist. In hill stations resting on sandstone he said the disease did not occur. Poona was at some elevation, on sandstone, but had no diarrhea. There was very little of the disease at Murree, and there was very little mica there. There was a large amount of mica at Darjeeling, and this station suffered enormously from hill diarrhea. There was no mica at Chungha Galli, and no hill diarrhea. Dyson stated that after Pasteur filters were installed at Darjeeling, through which the mica could not pass, the hill diarrhea no longer troubled the station. Again during the cutting of the Panama Canal, mica dust got down the throats of the workers there, and diarrhea attacked them. Mica lodged in the follicles of the alimentary canal and diarrhea resulted. If there elevation caused the diarrhea, why was it not present in Switzerland? The treatment was by corrosive sublimate. Mica caused irritation which the intestinal germs till further increased; corrosive sublimate killed the germs. With regard to the relation of hill diarrhea to sprue, some authorities held that they were the same diseases. But he had never seen in any case of hill diarrhea the mouth symptoms of sprue; neither had he ever observed the restriction of the liver dullness of sprue in hill diarrhea. He had never succeeded in curing any case of sprue with corrosive sublimate. Colonel Crombie stated that opium and ordinary astringents were without the slightest effect. The absence of bile in the disease caused fermentation of the intestinal contents, hence we must supply the ferments to the intestine.

**Long Periods of Latency in Parasitic Diseases.**—Dr. LOUIS W. SAMBON, Lecturer to the London School of Tropical Medicine, said the long incubation period which at times precedes the manifestation of sprue was a remarkable though by no means unique case of prolonged latency in parasitic diseases. Blackwater fever might likewise manifest itself for the first time in Europe several months after its endemic stations had been left. Sleeping sickness had manifested itself in negroes transported to the Antilles so long as three, five, and even seven years after removal from the tsetse-fly belts of the Congo. The morbid manifestations of hydrophobia appeared at times twelve or eighteen months after infection by the bite of a rabid dog. There were certain rare instances in which the period of incubation lasted two, three, and even four years. In an interview which he had been granted recently by the King of Italy, His Majesty, who took the keenest and most intelligent interest in scientific questions, related to him the case of one of his own gamekeepers in whom the incubation period of rabies had lasted three years. A very long period of latency was frequently noticed in leprosy. Hallopeau had published a case in which the first symptoms of leprosy had appeared thirty-two years after return from a country where this disease was endemic. In people harboring trematodes or nematodes there might be no signs of the presence of these parasites, or the morbid manifestations might appear only after several months or years. Such was the case with calculosis as a manifestation of *Schistosoma hæmatobium*, anemia as a symptom of uncinariasis, elephantiasis as an indication of infection with *Filaria bancrofti*, and the excursions of *Filaria loa* which might take place either at an early or late period in the development of this long-lived parasite. The length of the period of latency might be due to very different causes. It might depend on the numerical strength, virulence or location of the parasite, or on the resisting power of the host. Sometimes it might depend on the migration of the parasite from one region or organ to another. With some parasites the migration occurred at more or less definite periods, corresponding to certain stages of development; with others it took place in consequence of conditions as yet undetermined. Perhaps the most important factor was that of association with other pathogenic or nonpathogenic organisms, the asosciated organism rendering the tissues more or less vulnerable, or even conveying the quiescent parasite to a territory more favorable to its pathogenic activity. In the last few years we had discovered that ectoparasites played a very important rôle in the transmission of pathogenic microorganisms from without into the system through the skin. It was quite likely that some internal parasites within the alimentary canal or within the blood vessels might perform a similar rôle by conveying more minute organisms from one anatomical region to another. Possibly Castellani's trypanasome might be the means of the streptococcic invasion of the nervous centres which brought about the terminal symptoms of sleeping sickness. *Filaria bancrofti* paved the way for the microorganism which caused lymphangitis, and both together gave rise to elephantiasis. In conclusion, he wished to say that the long period of latency was not against the parasitic nature of prue, of which he was absolutely convinced.

Dr DAVID J. GALLOWAY of Singapore said he quite agreed with Dr. Sambon as to the parasitic nature of sprue. He could instance cases in which several inmates of a house infected each other with sprue. He had frequently seen the disease pass from husband to wife, or from wife to husband. He objected to the term "sore tongue" because the tongue was frequently affected without pain. One symptom seemed to have escaped notice, and that was the intense anemia which developed in cases of sprue. The red blood corpuscle count might be as low as 1,500,000 at times, while the hemoglobin remained high. With regard to treatment, he advocated the milk cure. With milk alone one soon got custard stools without any fermentation, and recovery was rapid. Intestinal antiseptics might be useful.

Dr. A. J. CHALMERS of Ceylon considered that cases of sprue were relatively few in Ceylon. Difference of opinion was very much a matter of diagnosis. His cases were

chiefly among Europeans. It was useless to discuss the nature of the disease without a knowledge of its pathology. He considered the liver to be the organ essentially at fault. He had obtained remarkable improvement from the administration of liver soup. This was no new remedy, but an old native method of treatment. He believed in the usefulness of intestinal antiseptics, but the liver soup treatment alone had given excellent results.

Dr. JOHN CAMPBELL GRAHAM of Deli, Sumatra, stated that sprue was very rare in Sumatra. There were other forms of stomatitis, but nothing like Indian sprue. The natives, however, gave the name of sprue to these cases. Dr. Graham read an abstract from a paper on sprue by Dr. A. Van der Scheer, who held that there was a causal relationship between appendicitis and sprue, and proposed the removal of the appendix.

Dr. F. O. STEDMAN of Hong Kong said he had been in practice in Hong Kong for some years. He did not agree with Cantlie as to the milk treatment of sprue. He was favorable to the administration of intestinal antiseptics, especially beta-naphtol. The white stools were not pathognomonic only of sprue; in Hong Kong similar white motions were also found in another disease. In Hong Kong diarrhea is frequent after the rains, and the water at that time becomes quite opalescent. He thought that these numerous cases of diarrhea in summer soon after the rains might be due to a micaceous deposit in water.

Lieutenant-Colonel ANDREW DUNCAN said that he could not agree with Cantlie as to the milk treatment, because he had found it beneficial in sprue; but he had found the meat treatment efficacious in cases which milk did not cure.

Dr. C. F. HARFORD of Livingston College, London, said that diarrhea was the cause of a great amount of invaliding in tropical countries. Some five hundred missionaries, returning home after an absence of variable periods in the tropics, all agreed that diarrhea was the most frequent and the most serious cause of ill-health in tropical and subtropical regions. The pathology of intestinal tropical diseases was but little understood, and required to be scientifically dealt with in the immediate future if we hoped to reduce the enormous amount of invaliding which occurs amongst Europeans in warm countries.

Dr. J. H. EBELL of Colombo, Ceylon, said that in Ceylon the native liver soup treatment had now become practically a routine treatment, and he could testify to its efficacy. The natives administer, besides the liver soup, a kind of curry made with the leaves of a certain plant and the fermented juice of the cocoanut palm.

Dr. W. L. STRAIN of San Paulo, Brazil, said that sprue was not a disease of West South America. During twenty years' residence in Brazil he had never seen a case of the disease. Of course, there was diarrhea, and, indeed, every newcomer to the city of San Paulo was attacked by this diarrhea. Although San Paulo was inland and 2,700 feet above sea level, he had never attributed the diarrhea to elevation *per se*. He thought it was caused by dietetic errors. The Italian physicians, some of whom were very able men, cured the disease by means of pills containing ox bile.

Dr. J. HUTSON of Barbadoes said that sprue was known in Barbadoes under the name of thrush. In recent years pellagra had become very prevalent in the West Indies, and had greatly obscured the diagnosis of sprue. In many tropical regions the meat treatment was no easy matter. Fresh meat was difficult to get, and was usually of inferior quality. He had obtained most beneficial results from a pure banana diet continued for three or four weeks. Corrosive sublimate in very small doses was frequently efficacious.

**Diarrhea From Flagellates.**—Dr. ALDO CASTELLANI of Ceylon contributed a paper with this title, in which he described two cases of diarrhea with semiliquid, brownish stools in which he had found enormous numbers of flagellates. The patients had no fever, no griping pains, and their motions did not contain blood or pus. The flagellates were of various kinds *Trichomonas hominis, Cercomonas, Lamblia intestinalis,* and *Entamœba undulans* (probably a developmental stage of *Trichomonas hominis*). Believing the diarrhea to be due to the flagellates, Dr. Castellani stopped all astringents and instead ordered a large intestinal irrigation of a 1-2,000 solution of methylene blue (three pints) to be used twice daily. Improvement was striking, and it was very interesting to notice how rapidly the flagellates had decreased and how many of them had completely or almost completely lost their motility and become globular in shape. Within two days the diarrhea ceased. Several authors had described cases of diarrhea probably due to flagellates, but by the great majority of authors the intestinal flagellates were considered harmless, an opinion based chiefly on the fact that these parasites had been found in healthy people. This was the same argument that had been used to deny the relation of amœbæ to a form of dysentery. He certainly admitted that flagellates had been observed in normal people, but he believed that the intestinal flagellates, though harmless when few, must have some pathogenic action when present in enormous numbers, as in his two cases.

**Beriberi.**—Dr. TERTIUS CLARKE read a paper on this subject, discussing the various theories concerning its etiology. He said the arsenical theory was based on the similarity of symptoms, and on the finding of arsenic in the hair and toenails of some patients; but the herpes, the pigmentation, and the painful feet of arsenical neuritis were not seen in beriberi. In addition to this the neuritis of beriberi was chiefly parenchymatous, while that of arsenic was chiefly interstitial. The rice theory had its main support in the almost complete immunity of Tamils from the disease in a country where beriberi was one of the three chief causes of death. These Tamils subjected their rice before husking to a preliminary boiling, while the other races husked their rice raw, and so it could become contaminated by the poison which was in the husk. This was not the only difference between the Chinese and the Tamils, for the former rarely took hot things with their rice, whereas the Tamils always took a quantity of pungent things containing essential oils, which it would be reasonable to regard as preventives. The place theory supposed that the virus existed in certain places or gangs, some considering that the organism, others that only the toxin, produced by the organism gained entrance to the system Only conjectures could be made as to how the organism or toxin entered the system. The theory of Hamilton Wright was that beriberi was "an acute infectious disease having a definite primary lesion" in the stomach and small intestine, and that the causal organisms might be ingested in any food and drink accidentally contaminated and might "multiply and produce a toxin both in the contents and walls of the affected stomach and in the small intestine." The chief support of this theory was the finding of gastroduodenitis in all cases in which death had occurred in the early stages of the disease. Bearing on the rice theory, Dr. Clarke related an experience of his own. He was in charge of a hospital and of an Asylum for Decrepit Vagrants in Lower Perak. The hospital had been in use for several years; the asylum, though an old building, had for some time been empty. The hospital and asylum were about three hundred yards apart; the soil, air, and water supply were the same. The hospital had cement floors and very well ventilated wards; the asylum had raised wooden floors and very badly ventilated wards There were about sixty Chinamen in the asylum, and about thirty in the hospital daily. The food in the two institutions was similar in quantity and quality, and was supplied by the same contractor. The conditions at the hospital were, on the whole, far better than they were at the asylum except for the one fact that the clothing, bedding, and utensils at the hospital had been in use for some time, whereas all these things at the asylum were absolutely new. Beriberi cases were admitted into both institutions, but of thirty cases in the hospital between the middle of

November, 1903, and the end of the year, six originated in the hospital in men admitted for other diseases, and twenty-nine of the thirty patients died, showing an extraordinary virulence. During the same period at the asylum no beriberi patients died and no new cases occurred among the inmates. After very thorough disinfection of the hospital which included boiling all clothes, perchloriding the bed-boards, floors, and walls, and changing the patients around so that the Tamils occupied the Chinese ward and the Chinese the Tamil ward, no more cases arose. No change was made in the diet. No Tamils acquired the disease, though their rice was the same and actually cooked in the same vessel with that for the Chinese. It might be noted, however, that they had hot curry-stuffs and no pork.

Dr. Clarke said it was quite the exception for dressers, or even for ward attendants, who might sleep every night in beriberi wards, to acquire the disease. He had known a Chinaman who had been a ward attendant for nine years (and who must have slept many hundred times in a ward containing thirty or forty beriberi patients) leave in order to go tin mining, and come back into hospital in a few months with beriberi. These attendants slept and worked in the beriberi wards, and their diet was the same as that of the patients; the chief difference in the conditions being that the attendants had their own bed-boards, blankets, and mosquito curtains, which were not changed for those of the patients, while these things were interchangeable among patients. If the infection was within a hospital ward, it should be looked for in the bed-board, clothing, or bedding. It was not easy to see how it could lie in cement floors, in lime-washed brick pillars, or in walls made of "bertam," which allowed the air to percolate freely through. The bedbug was a most difficult thing to keep out of hospital bed-boards; and though the infrequency of the disease in towns, as compared with the mines, and the rarity of the disease in Tamils, might suggest that this insect was not the cause, yet it seemed to him that the so-called "place" will probably come down to the bed-board, clothing, or bedding, and that a not uncommon inhabitant of these things might have somethnig to do with it. A few experiments to obtain infection of monkeys by the bite of bedbugs from the bed-boards of beriberi patients proved negative.

Dr. R. Tanner Hewlett of London mentioned two patients with beriberi admitted into the Seamen's Hospital, Greenwich, who rapidly improved when treated by subcutaneous injections of strychnine, 1/30 to 1/50 grain, twice daily alternately into each thigh, *i.e.* each leg receiving one injection of strychnine daily. He thought these two cases emphasized the value of the local use of strychnine in paresis, a form of treatment which had been advocated in infantile paralysis by Dr. Leonard Gutteries and others.

Dr. Hamilton Wright said that beriberi was an acute or subacute infectious disease due to a specific organism that might be ingested in any food or drink accidentally contaminated. After gaining an entrance into the alimentary canal, the organism multiplied in the contents of the stomach and small gut, but chiefly in the contents of the duodenum; there it elaborated a toxin which, being absorbed, poisoned certain afferent and efferent neurons to different extents and in different degrees, and thus gave rise to a group of symptoms which could be classified as acute pernicious, acute, and subacute beriberi. The probable duration of the active stage of the organism was from two to six weeks; after its active stage had ceased and its virus had been eliminated the paresis or paralysis it had engendered persisted. For this persistent paralysis he proposed the term "beriberic residual paralysis." He maintained that our knowledge of beriberi had been erroneously founded on the study and statistics of the residual effects of the disease (beriberic residual paralysis) and not upon the disease itself (acute pernicious, acute, and subacute beriberi). The position would be the same with regard to diphtheria had we based our conceptions of the disease upon postdiphtheritic paralysis. His theory that beriberi was an acute infectious disease having a definite primary lesion was based not only on clinical evidence, but also on indisputable post-mortem evidence.

Dr. Louis W. Sambon said he had read with great interest Dr. Wright's reports on beriberi, and he considered that the latter's careful and painstaking researches in the Malay Peninsula had elicited many important facts concerning the epidemiology of the disease. But he could not follow him when he stated that what hitherto had been called beriberi was only a sequela—a "residual paralysis"—and that the true disease was a duodemitis of short duration—an acute disease which he ascribed to an intestinal bacterium that he had neither cultivated nor inoculated, but only found post-mortem in the contents of the bowel. To Dr. Sambon the neuritis was the essential feature of beriberi; and, considering that in each case, and at different periods during the course of the disease, different sets of nerves were implicated, and that while some nerves recovered others degenerated, and that even within the same nerve, while some fibers degenerated others went through a process of regeneration, he was inclined to believe that the causative agent of the disease was to be found in the diseased nerves. In rabies the specific organisms were found in the spinal ganglia, and at times (in furious forms of the disease) they were very numerous in the cortex of the brain and in the cornu ammonis. In leprosy also the bacilli were frequently found in the diseased nerves. As to a possible agent of transmission, he thought that notwithstanding Dr. Clark's negative experiments the bedbug was the only one which seemed to fully agree with the peculiar epidemiology of beriberi. It also explained the difficulty of eradicating the disease from infected collective dwellings. Finally he wished to draw attention once more to the latency and recurrence of the disease in those who had contracted the infection. The relapse of beriberi, at a certain season of the year and under certain conditions, was analogous to that of malaria and explained many obscure points in the epidemiology and natural history of the disease.

## SOCIETY OF MEDICAL INSPECTORS OF THE CITY OF NEW YORK.

*Regular Meeting, May 9, 1905.*

The President, Dr. Augustine C. McGuire, in the Chair.

**Prophylaxis in Diseases of Children.**—Dr. Floyd M. Crandall read this paper, treating of prophylaxis in children from the viewpoint of the medical practitioner and the sanitarian. He quoted Holt, as saying that it is possible to prevent the majority of the diseases of children. A great many children's diseases were due to improper feeding, especially the diseases occurring during the first three months of life. Prophylaxis in children's diseases had made great strides during the last thirty years, and the mortalities of all ages had been greatly reduced. The great difficulties physicians and sanitarians met in their work of prophylaxis were ignorance, prejudice, old-fogyism, and religious delusions such as Christian science. There was still a certain amount of hatred of interference, and "love of personal liberty" opposed to all sanitary regulations. The requirements for a successful health officer were patience, tact, and courtesy, and equipped with these he was more likely to effect his mission.

**The Physical Condition of School Children.**—Dr. John J. Cronin read this paper, in which he reviewed the work of the department in the public schools in accordance with the new system which involved a thorough physical examination of each pupil by the medical inspector of the Health Department. If any disease or deficiency of sight or hearing, etc., was found, the child's parents were notified and referred to the family physician. The speaker said that the new system was rapidly producing beneficial results and that over 50 per cent. of the children found with defective vision had

procured glasses on the advice of the inspectors. In the physical examination, especial attention was paid to the child's nutrition, to cardiac and pulmonary diseases, to nervous affections, deformities of limbs, spine, or chest, and to throat and nose affections. The work, in the speaker's opinion, would bring forth rich fruits both in the health and in the education of the children, and would be of great benefit to the succeeding generation, as the children of today would demand better conditions for their children. It was to be hoped that any tuberculous children detected would receive proper care in public or private institutions or sanatoria, and would be taught separately from healthy children; also that pupils with heart disease would be dealt with gently as befits their condition and would not be crowded too much mentally. Care must also be taken that such children be debarred from violent athletic contests. Pupils with chorea and with other nervous disorders were also best treated and educated separately. The effect of adenoid growths and of hypertrophied tonsils on the child's physical and mental development was well known, and the removal of these structures, when indicated, was one of the great objects of these examinations. About 33 1-3 per cent. of all children examined had defects of vision corrigible by glasses, and this largely accounted for the great proportion of backward children in the New York school-system. Physical defects were largely responsible for truancy and other bad habits, and truancy was the first step on the downward path leading to crime and immorality. It was as hard for a truly healthy body to do or think wrong as it was for a defective body and unhealthy mind to do or think right. Some of the unhallowed money now so much discussed would be well spent in procuring glasses for the poor children of the tenements who need these aids to mental development. By caring for the child at school mentally and physically, we might hope to lessen the burdens of the state, and reduce the ranks of the paupers, the cripples, the consumptives, the insane, and the criminals.

Dr. Jacob Sobel said that in pursuing the work of prophylaxis in the school it was very important to secure the full cooperation of the principals. Propyhlaxis in school life was directed towards the prevention mainly of the infectious diseases, while in earlier life was the time to prevent errors of nutrition and development. He believed that tonsils that were large in size and presented a good surface to infection should be removed as a prophylactic measure, even though they did not obstruct respiration.

Dr. Charles Herrman suggested that each teacher in the schools receive a card of instructions on the methods of dealing with contagious cases developing at school, the rules for inspection, etc., so that they might become thoroughly familiar with the work of the department and would fully cooperate with the inspectors. The early recognition especially of the milder contagious diseases should be systematically promoted by sending all cases where there was the slightest suspicion to the inspector for examination.

Dr. E M. Thompson took exception to Dr. Cronin's statement that pulmonic and cardiac cases should be included in the truant and criminal class. In his experience such children were usually exceptionally bright. He thought that more time should be given to the early detection of incipient contagious cases instead of waiting for the teachers to make diagnoses of already developed cases.

Dr. De Santos Saxe said that since the new system of examination had been begun, there was a great deal more appreciation on the part of the principals for the work of the department. The school authorities were now realizing more than ever the true aims of the Health Department, and the two branches were working together with less friction than formerly. While a great deal would be done, no doubt, for the children now examined, yet the ultimate results of the work as outlined by Dr. Cronin would be seen only in succeeding generations. No one realized better than the inspectors the handicaps which they encountered in the prejudice and ignorance of the average layman, but gradually the public was becoming educated to regard the Health Department, not as an arbitrary ruler, not as its arch enemy, but as that part of the government that sought the welfare of the community by preventing disease.

Miss McCann, speaking for the Association of Women Principals, assured the Society of the hearty cooperation of that body in the new work of the Health Department in the schools, and said that the women principals some time ago petitioned the Board of Education to establish a similar system of physical examination, especially in the lowest grades. She thought that the best time to examine pupils was upon their entrance into the 1A grade. Then was the time to detect defects and to prevent trouble later.

Dr. Floyd B. Ennist said that the effects of the work now undertaken in the schools were difficult to overestimate, when one could find, as he had, a child who could not read the top letter of the Snellen twenty-feet test-card, and who could read with ease after securing glasses. One such result alone, he felt, was worth a month's work, and he was only sorry that in his own childhood days such examinations were not made, as he certainly would have been saved a great deal of trouble if he had had glasses early enough. It was a pity, he thought, that some philanthropist like Carnegie did not see fit to enable physicians devoting themselves to humanitarian work of this kind to give their time to it without struggling for a livelihood. The results of this work would be a greater monument to a philanthropist than all the libraries in the country.

Dr. Ghertler said that he had found three children with cardiac disease in one of the schools committed to his care, in whom he had the opportunity of noting the bad effects of violent exercise. He had observed these children before and after the routine lessons in physical training, and had been impressed with the dyspnea, the palpitation, and the other signs of cardiac exertion which they exhibited. He therefore pleaded for a careful exclusion of such children from any but the mildest physical exercises.

Dr. Cronin, in closing the discussion, said that he was obliged to differ from Miss McCann, and that the best time to examine school children was when they had reached the upper primary grades, when they showed signs of strain in various ways; when mentality could be better judged, and when deformities showed more clearly. Dr. Thompson could not have understood him correctly, as the speaker had not included the cardiac and pulmonary cases among the truants and the criminals. As a matter of fact, statistics showed that there were few cardiac cases among the mentally defective, and no pulmonary cases among them. The point he wished to make was, that these children should not be pushed or driven beyond their strength in their studies, or in exercising. He agreed with Dr. Sobel in advocating the removal of tonsils of large size irrespective of the question as to whether they produced any symptoms or not. They were bound to cause trouble sooner or later.

---

### Chicago Surgical Society.

At the April meeting, Dr. John C. Munro of Boston, read a paper by invitation, entitled, "Lymphatic and Hepatic Infections Secondary to Appendicitis." He offered the following suggestions: (1) Lymphatic and hepatic infections were more common than we realized. (2) The two infections were frequently associated, and one type might be the source of origin of the other. (3) In certain cases of hepatic abscess, the source of infection, whether through the portal canals or through the lymphatics, could not be determined either clinically or at operation. (4) The type of infection did not depend upon the gravity of the originating appendicitis. (5) Subphrenic infections must not be isolated in a class by themselves, as they depend on both lymphatic and hepatic infections, and *vice versa*. (6) Hepatic infections were not uniformly distributed, even when originating in the portal tract, the left lobe being solely affected at times. (7) The prognosis of lymphatic, including the subphrenic, infections was better than that of hepatic, but when the latter were secondary to lymphatic

or direct mechanical invasion, the outlook was more favorable than in the true portal invasions. (8) The most important clue in making a diagnosis was the recognition of the causative appendicitis, and the elimination of this possible cause was necessary in dealing with obscure hepatic invasions in the presence of plasmodia, the Widal reaction, etc. (9) Early recognition and removal of the inflamed appendix might abort a secondary infection of the type considered here, but the corollary did not necessarily follow. (10) The characteristic signs and symptoms were well established in typical cases, and should form a basis for diagnosis in atypical cases.

Dr. Jacob Frank described "A New Method of Incising and Suturing the Liver to Reestablish Its Continuity and for the Control of Hemorrhage." Eighteen experiments on dogs were detailed. Two consisted of simply incising the liver through its entire thickness, without any suturing or other attempt to control hemorrhage. Both dogs recovered. In the remaining sixteen experiments, the author pursued the following plan: When a portion of the liver was to be removed in a transverse direction, a wedge-shaped piece was removed transversely to the viscus, leaving the organ with two flaps forming a trough. The flaps were then quickly coaptated, and with a long, non-cutting needle, threaded with a medium heavy catgut, a continuous suture was taken, the sutures alternating, one carried through the liver tissue near the bottom of the trough, and one superficially, until there was complete closure. It required very slight tension to approximate the flaps. The main object was to bring the flaps together for the purpose of obliterating all dead space. When a portion of the liver was to be removed in a longitudinal direction to the viscus, a wedge-shaped piece of the entire thickness of the liver was cut out longitudinally, thus removing the desired part. The broad, raw surfaces left by the removal of the wedge-shaped portion were converted into troughs, which was accomplished by the excision of wedge-shaped pieces. The troughs thus formed had two flaps. When the operation was completed, the raw surfaces of the original V left were transformed into smooth, continuous liver tissue, assuming the form of liver borders, and the V space left persisting as a notch. This method of excising the liver facilitated easy suturing, and did not require any tension on the suture to coaptate the flaps. Hemorrhage was successfully arrested, and the continuity of liver surface was reestablished. No drainage was used in any of the experiments.

---

### Chicago Surgical and Chicago Medical Societies.

At a joint meeting of these societies, held June 7, 1905, Professor G. N. Calkins, of Columbia University, and Biologist to the State Cancer Laboratory, Buffalo, by invitation, spoke on the biological aspect of carcinoma. He mentioned the theories in vogue which have to do with the explanation of the stimulus of division energy of the carcinoma cells. Of the various theories advanced, he considered only two: (1) Marchand's theory, which he said was analogous to the stimulus of the gall-producing insect poison on plant cells; and (2) the parasite hypothesis. They had in Buffalo some 200 mice with carcinoma. The original tumor mice, which Dr. Gaylord brought with him from Prof. Jensen's laboratory, in Copenhagen, in February, 1904, died on the way from New York to Buffalo. The tumors were removed and put on ice. In three days, when mice were obtained, the tumors were transplanted into normal mice. About forty per cent. practically of the transplantations took, and a large number of mice developed carcinoma. The growths made their appearance in from three to five or six weeks after inoculation, the tumor mice ultimately developing symptoms of cachexia, followed by death. The tumors that developed varied in size from one-third the weight of the mouse plus the tumor to one-fifth. These tumors were transplanted from mouse to mouse nine successive times in the Buffalo Laboratory. Prof. Jensen had similarly transplanted the tumors from mouse to mouse for a period of two and a half years before Dr. Gaylord brought them from his laboratory to Buffalo, so that altogether there had been, in all probability, about thirty to thirty-five generations or transplantations of this tumor. These tumors were merely metastases from the original growth. The cells of the old tumor in each successive new environment were stimulated to grow and develop into a new tumor. According to the Marchand hypothesis, the primary stimulus which the first mouse received was a poison which originated from deranged metabolism, from malnutrition, or from other product of morbidity in the organism of the mouse. Were we to assume that there was formed in every mouse morbid products which carried on the stimulus to the division energy of the cells? In other words, could the organism produce a toxin which acted as a continued cumulative disease factor? On the other hand, according to the parasite hypothesis, we might assume that the primary tumor of the original mouse was caused by poison from some parasite. The advocates of the parasite hypothesis were forced to the conclusion that the parasite must be ultra-microscopic. The speaker did not wish to advocate that view, although he said it was gaining ground throughout the scientific world. In November of last year the disease tumor began to deteriorate; and the mice then showed signs of natural immunity and ability to throw off the disease.

A great many mice spontaneously recovered. They had had altogether over a hundred and fifty cases of spontaneous recovery from true carcinoma in mice. They thought the tumor material was growing physiologically old, and that it would die out and their means of experimentation would be lost. A tumor, therefore, was transplanted to a new strain of mice, and the virulence of the cells was restored, so that the mice died in from three to five weeks after inoculation. Dr. Clowes, chemist of the laboratory, conceived the idea that the blood from such a spontaneously cured mouse might carry immunity. He inoculated some mice having tumors of small size with the immune blood from a mouse that had spontaneously recovered. This was done in a number of cases, and six tumors disappeared after the use of this immune serum. Experiments had shown that immunity thus acquired had been efficient up to the present time, and had carried with it protection to the mice against reinfection. Experiments were tried subsequently in a slightly different form. In one such experiment, for example, forty-five mice from the same source were taken; twenty-three of them were treated with cancer mush plus the immune serum from the mice which had spontaneously recovered; and twenty-two of them were treated with cancer mush plus the normal blood of normal mice. The only difference between them apparently was the immune factor from cases in which the mice had spontaneously recovered. In the twenty-three mice treated with this immune serum, three developed tumors. In the twenty-two mice that were treated with normal blood plus the serum, ten tumors developed, or about the proportion of tumors successfully produced by the inoculation method.

This, in brief, he stated, was the position, from a biological point of view, of the cancer problem to-day. It was not known what caused the stimulus. It was not known that there was a parasite in cancer. It was not known that a specific poison produced in any way was the cause of carcinoma; nor was there sufficient evidence on biological and cytological grounds to justify the hypothesis of Farmer, Moore, Walker, and Bashford. Progress, however, was being made.

Dr. E. Wyllys Andrews read a paper in which he discussed the past and future surgery of carcinoma. Dr. William Allen Pusey read a paper on "The *X*-Ray in the Treatment of Carcinoma."

PHILADELPHIA COUNTY MEDICAL SOCIETY—NORTH BRANCH.

At a stated meeting, held May 16, Dr. HENRY LEFFMANN read a paper entitled "Dangers from the Domestic Use of Illuminating Gas and the Means of Avoiding Them." He pointed out that the obnoxious odor of old-fashioned coal gas was to a great extent a safeguard in its use, whereas the present form of illuminating gas, because of the larger proportion of water-gas it contained, is so nearly odorless that its presence is not readily detected by the sense of smell. The poisonous character of water-gas also demands the greater caution. Natural gas contains only 0.5 per cent. of carbon monoxid, coal-gas 6 per cent., and water-gas 45 per cent. With the object of diminishing the dangers from the use of illuminating gas for various domestic purposes, Dr. Leffmann suggested that the sale of inferior rubber hose for connecting gas stoves and heaters should be prohibited by law and that in no case should stop-cocks for turning the gas on and off be attached at the service end of such connection. He contended further that the burners on gas cooking stoves should be constructed on scientific principles, and he argued for rational cooperation between manufacturers of gas and gas stoves on the one hand, and physicians and sanitarians on the other hand, in establishing adequate safeguards to protect the public in the domestic use of gas. Dr. W. M. L. COPLIN presented a c. mmunication entitled "The Medico-Legal Relations of Gas Poisoning." Dr. WILLIAM S. WADSWORTH read a paper entitled "The General Characteristics of Gas-Poisoning, as Seen in Philadelphia." He contended that laws should be enacted with reference to illuminating gas and gas fixtures and attachments similar to those relating to sanitary plumbing. Landlords should be subjected to fines for providing imperfect fixtures, and it should be an offense to sell imperfect or inferior gas rubber tubing or gas burning apparatus of any kind for domestic use. Many deaths could be attributed primarily to imperfect fixtures, improperly constructed gas ranges or stoves, and inferior rubber-tube connections.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

At a st ted meeting, held June 7, Dr. ROBERT N. WILLSON, JR., read a paper entitled "Three Cases of Cerebrospinal Meningitis, Probably Due to the Meningococcus." In two of the cases pneumonia existed. Pneumococci were found in the fluid obtained by spinal puncture. All of the patients recovered. A fourth case of cerebrospinal meningitis was cited, in which the fluid obtained on puncture was sterile. Dr. JOHN B ROBERTS read a paper entitled "A Fatal Case of Bacillus Pyocyaneus Septicemia After Surgical Operation." The patient was a girl, nine years old, who required a plastic operation about the shoulder. Suppuration took place, and symptoms of septicemia developed. The pus was observed to have a blue color, due to the bacillus pyocyaneus. Death resulted, but post-mortem examination could not be obtained.

**Tuberculosis of the Peritoneum and Adnexa.**—P. Bégouin calls our attention to the tendency to regard tuberculosis of the peritoneum as always secondary to that of the adnexa. The result of this view has been the conclusion that in order to obtain a cure it is necessary to remove ovaries and tubes. On the other hand, many cases have been cured by simply opening the abdomen, without removal of the tubes and ovaries. The author details a case of tubercular peritonitis so advanced that it was decided impossible to remove the adnexa at the time of the operation, and the abdomen was closed; this patient entirely recovered. Many other similar cases have been published by other authors. The author claims that we should be more conservative in our treatment of such cases, and should not do a double castration in a young subject, thus unfitting her for married life, without careful consideration of the question whether cure is not possible without this sacrifice of the genital organs.—*Journal de Médecine de Bordeaux.*

## Books Received.

*While the* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

TWENTY-EIGHTH ANNUAL REPORT OF THE BOARD OF HEALTH OF THE STATE OF NEW JERSEY AND REPORT OF THE BUREAU OF VITAL STATISTICS, 1904. 8vo, 494 pages, illustrated, muslin.

PROCEEDINGS OF THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION AT THE SIXTIETH ANNUAL MEETING, held in St. Louis, Mo., May 30 to June 3, 1904. 8vo, 470 pages, illustrated, paper.

CURRENTS OF HIGH POTENTIAL OF HIGH AND OTHER FREQUENCIES. By WILLIAM BENHAM SNOW, M.D. 8vo, 196 pages, illustrated, muslin. Scientific Authors' Publishing Co., New York. Price, $2.50.

JUDISCHE AERZTE UND IHR EINFLUS AUF DAS JUDENTUM. Von Dr. SIMON SCHERBEL, 8vo, 75 pages, paper. J. Singer & Co., Berlin, Germany.

MEMORIA DE LOS TRABAJOS EJECUTADOS EN EL CONSEJO SUPERIOR DE SALUBRIDAD EN EL ANO DE 1901, 1902, 1903, AND 1904. Folio, pages, 221, 236, 234, 288 paper.

THERAPEUTICS: ITS PRINCIPLES AND PRACTICE. By HORATIO C. WOOD, M.D., LL.D. Twelfth Edition. Thoroughly Revised and Adapted to the Eighth (1905) Edition of the United States Pharmacopœia. By Horatio C Wood and Horatio C. Wood, Jr., M.D. 8vo, 907 pages, illustrated, muslin. J. B. Lippincott Co., Philadelphia.

**A Note on the Condition of the Tendo Achillis Jerk in Diphtheria.**—J. D. Rolleston bases his paper on 100 cases of diphtheria in which the tendo Achillis jerk was investigated. He presents the following summary: The tendo Achillis jerks are affected in a considerable proportion of all cases of diphtheria, though less frequently than the knee-jerks. The frequency and extent to which they are affected bear, like albuminuria and paralysis, a direct relation to the character of the initial faucial attack. They are completely abolished in all cases of diphtheritic paraplegia. Their absence may be the only evidence of loss of motor power in the lower limbs. Like the knee-jerks, they are liable to be affected at an early stage of the disease, and to remain absent after disappearance of all diphtheritic paralysis, properly so called. Like the knee-jerks again, they may be unequally affected on the two sides, and, like the former, they may be unusually brisk before they become sluggish, and finally disappear. The Achillis jerk, like the knee-jerk, after it has been lost may reappear on one side before it does so on the other.—*Brain.*

**Cysts of the Vagina.**—Voituriez tells us that the frequency of vaginal cysts is considerable; 50 cases were found by Neugebauer in his own practice. A cyst of the vagina is a fluid tumor, of some size, growing sufficiently large to demand interference. They are to be distinguished from minute cysts, the result of endometritis. They occur in young women, frequently after an accouchement, and they may also be found in the very young and even congenital. They are single or multiple; are generally lateral; are often oblong; they are paracervical, retrovulvar or occur in the middle of the vagina. They originate within the vagina, and project through the vulva. They may be as large as an egg or even as a child's head. They grow in the thickness of the vaginal wall, and thin the mucous membrane, as they grow, so that the wall becomes fine and transparent. The wall of the cyst is composed of connective tissue of the fine fibrillar variety and contains usually muscular fibers. The inner surface is lined with cylindrical stratified epithelium, and may be ciliated. The contents is variable, generally transparent, and viscid, or yellow; it may be purulent as the result of inflammation. They may render coitus difficult and painful, and the diagnosis is made by vaginal examination. They do not tend to regression, but continue to grow and prevent function until operation is undertaken for relief. —*Journal des Sciences Médicales de Lille.*

**A Danger in Motor Driving.**—J. W. Dunbar Hooper warns his readers of one of the dangers due to improper action in starting a motor carriage, which results in a fracture of the radius and ulna. The object of revolving the flywheel is to overcome compression and start the piston working in the cylinder. The electric spark ignites the naphtha at a definite moment. If the explosion takes place too soon a "back fire" takes place, and the handle moves suddenly and forcibly in the opposite direction. If the handle is firmly grasped the force is exerted on the wrist. The handle should be grasped only with the fingers, and not the thumb of the hand, so that the handle is easily released when this unexpected movement takes place. There should be a steady pull upward, so as to get the hand over the dead center in its top position, and there it should stop, the hand not going beyond that point while grasping the handle, and on no account should the handle be forced down.—*Intercolonial Medical Journal of Australasia.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service during the period from August 19 to September 8, 1905:

### THE INDIVIDUAL TREATMENT OF DIABETES MELLITUS.*

By HENRY S. STARK, A.M., M.D.,

NEW YORK.

The idea it is intended to convey by the phrase "Individual Treatment," that I have taken the liberty of coining, is a consideration of the individual and his physical condition as a separate existence in contradistinction to the rules of treatment as collectively formulated that have no regard for individuality, which in the case of diabetes, is of the greatest consequence. In other words, the treatment of the individual is meant rather than that of his disease. Time and again in treating diseases, the failure to individualize has netted results that have been disappointing, while the tendency to generalize along beaten paths has abridged our therapeutic resources very materially, and at the same time contributed to bring a disease into undue prominence, at the expense of the patient, who was lost sight of, in the aggregate. This omission in the treatment of diabetes has manifested itself in a deplorable scarcity of specific medication, and in a notable failure to cut short, blot out, or lessen the frequency of its occurrence. Therefore, in treating persons suffering from diabetes, the physician who forsakes the tenets of the text-books, and the precepts of the lecturer, and who individualizes, classifies, and separates his cases, will be rewarded with better results than will he who casually prescribes an opiate and religiously prohibits carbohydrates. We are so apt to forget that therapeutic principles in their practical application must be modified to suit the exigencies of the individual cases, and that they must have a due regard for the modification of disease, as manifested in different individuals, and in the same subject under varying constitutional conditions. This dictum is doubly true for the disease under consideration, for the reason that it occurs under different circumstances in different subjects, varying in character and severity within wide limits, and therefore calling for such distinctive modifications in treatment, that the individual treatment of types of different groups may be quite at variance.

The natural history of the disease itself, its intrinsic tendency to chronicity, the failure of nature to effect a spontaneous cure, the alarming frequency of its occurrence, the vacillating state of our mind as to its pathology, the notorious impotency of most drugs, all combine to invest this disease with an importance and interest, as far as treatment is concerned, second to no other.

The old classification into mild, moderate, and severe types, which is based on the quantity of sugar in the urine and its tendency to disappear under a strict dietary regimen, is too arbitrary to be of much service in treating individual cases; while, in the light of our new knowledge of physiological functions and of the comparative fuel values of different classes of foods, such a classification is untenable. As proof of this claim is the everyday experience of meeting with cases of high sugar percentages accompanied by mild symptoms, and conversely, cases of low sugar percentages accompanied by severe symptoms.

Such a classification, while it has a certain prognostic value, entirely ignores the nutritive value of food elements, nor does it take into consideration the fact that the excretion of glucose in urine is not in itself incompatible with the enjoyment of health, and secondly, that the disappearance of the sugar is not yet proof that the patient is cured of diabetes. As a matter of fact, the organism actually requires for its maintenance carbohydrates for the repair and growth of its tissues, and for the production ot heat and muscular force. This necessity for carbohydrates is so emphatic that directly they are proscribed, the system draws upon the nitrogenous elements of food to supply the missing component, showing that if a sufficiency of carbohydrates for the needs of the system be withheld, the digestive organs are compelled to seek them from other sources. Thus we know that even under an exclusively nitrogenous and fatty diet, sugar may continue to appear in the urine. The system seems to crave for carbohydrates, and resents the withdrawal of them by the appearance of morbid states. I have seen a number of diabetics in whom the most persistent subjective symptom was muscular fatigue and pain, who were relieved only by the exhibition of a measured amount of carbohydrates.

The classification alluded to above, which has found its way into text-books, should, it seems to me, be therefore discarded, on the ground that the severity of the pathologic process cannot be estimated by the amount of sugar in the urine.

Another classification with which we are familiar is one based on the presumed seat of the lesion, namely, into hepatic, pancreatic, cerebral, myogenic, and the nervous variety. Concerning this classification, a moment's consideration will make it clear that this division is likewise objectionable.

Firstly, we do not with any degree of certainty understand the pathogenesis of the disease; secondly, the physician has not at his command sufficient clinical data to make a differential diagnosis between these types, and thirdly, the clinical pictures of these heterogeneous types ofttimes simulate each other to such an extent that an attempt at any such distinction must be mere erudition.

In the treatment of individual cases, therefore, it is more advisable to ignore the classifications in vogue, while it will be more profitable to direct our efforts against the morbid phenomena of the disease, as exemplified in individual cases. Unless this is done, treatment will become mere routine and dependent upon principles based on speculation as to the nature of the disease.

To insure the results outlined in this paper, a

*Read at the June meeting of the Harlem Medical Society, N. Y.

study of the following items, is indicated; to wit, (1) The power of assimilation for carbohydrates, which is readily ascertained by current methods. (2) The general physical state of the patient, whether anemic, plethoric, obese, or emaciated. (3) The mental attitude of the patient, whether depressed, hopeful, negligent, or indifferent. (4) The patient's ability to maintain weight. (5) The state of his digestive and assimilative functions, whether there is present an insufficiency, an atomy, or otherwise impaired function. (6) His ability to maintain a nitrogenous equilibrium, as relatively determined by a comparison between the specific gravity of the urine, and amount of urea excreted on the one hand, and on the other, the amount of digested proteid food. (7) The patient's age, physique, occupation, and mode of life, whether old or young, robust or frail, engaged at hard or easy labor, leading an active, strenuous, or sedentary life. (8) The presence of complications, particularly a nephritis, myocarditis, or arteriosclerosis. (9) His natural preferences for foods and beverages.

All the factors must be carefully noted with a view of treating each case on its own merits. The superiority of this method of treatment, while in no sense a radical departure from other methods, cannot be questioned, as the results of treatment speak for themselves. For it is no vain boast to declare that the greater success attending the treatment of diabetes to-day, is due rather to an intelligent management of cases on the lines here indicated, than to the use of remedial agencies.

Diabetism, as now observed by me in public and in private practice, is no longer the fell disease it was ten and fifteen years ago. The disease to-day has been robbed of many of its destructive capacities, nor do we meet so often with such revolting and aggravated types. The diabetic of to-day, generally speaking, lives longer and more contentedly, suffers fewer dietary privations, need not religiously practice total abstinence from sugars and starches, and from liquors; extensive dermatoses, such as furunculosis, and carbunculosis, occur less frequently, diabetic coma is amenable to treatment and can be at times retarded, while diabetic gangrene can be at times belated or limited in its ravages; recoveries after surgical operations occur more often.

I think you will sanction my optimism anent the progress made in alleviating the symptoms of diabetes, and I believe you will agree with me that the proximate cause of this improved state of affairs is, as has been outlined in the subject matter of this paper, the application of exact methods combined with a close concern of individuality in disease.

Inasmuch as the pathogenesis of the disease is still in question, our efforts must be directed against symptoms alone. Unfortunately, we have no specifics, not even a remedy, in which reliance can be placed, as a curative agent. All who look to certain drugs, therefore, as antidotes to the disease will be doomed to disappointment, and yet a number of drugs have been extolled from time to time for their usefulness.

I have personally experimented with a number, giving each a fair trial, and have been finally forced to discard each in turn. Among such, the following are a few: Arsenic and its preparations, salicylate of soda and aspirin, permanganate of potassium in fifty consecutive cases, which were reported in a previous paper, the coal-tar preparations, sulphate of sodium, iodide of potassium, bichloride of mercury in cases in which a history of syphilis, inherited or acquired, was given, jambul, yeast in quite a large number of cases.

The results in all of these trials were carefully watched and considered. Sometimes it would appear as though a certain amount of reliance could be placed in them, but the improvement was of short duration, so that the final judgment had to prevail that the use of drugs, as curative agents, was very questionable, and that the search for a specific was a seemingly hopeless task. I have had better results, however, in the employment of special drugs for the amelioration of special symptoms, and in the choice of these agents, I was guided by an interpretation of the origin of the symptoms and the *modus operandi* by which these made their appearance; for example, if in a given case I believed that the clinical picture indicated an hepatic insufficiency, efforts were directed against the liver, as the *fons et origo* of the disease, with the result that more than one diabetic, who presented marked gastro-intestinal symptoms was relieved with sulphate of sodium, or calomel, or bismuth. Again, if I found a condition of chronic anemia, a resort to chalybeate preparations gave more satisfaction than did the perfunctory employment of opium. Or, if in another set of cases the nervous element predominated, with disturbed sleep, irritability, migraine, neuralgias, psychopathia, unusual solicitude of the patient as to his physical state, and an indifference to his obligations, I supplemented the treatment with nerve tonics, such as a combination of the following preparation: Sodium bromide ʒss, sodium phosphate ʒi, dissolved in a mineral water and taken at bedtime, until the nights became calmer, the temperament improved, the pains were alleviated, and the whole mental attitude was improved. I have never allowed myself to believe that there was any one drug, not even excepting opium, which could be relied upon to cure diabetism, and I have always been sceptical regarding the extravagant claims made by some observers for certain drugs, because I believe such claims were based on hypothetical views regarding the nature of the disease, and on the ground that these observations do not take into consideration the essential fact that a glycosuria is merely a symptom, and its disappearance does not mean that the patient is cured of his diabetes, as the constitutional vice may still persist in other forms.

In a number of cases, which gave a history of acquired syphilis, iodides and mercury were employed with a view of favorably modifying the course of the diabetes, but I must confess my utter failure to establish a possible connection between these two affections. In the same lines of investigations lithia salts were employed, when a distinct history of gout was manifest, aspirin, when a rheumatic diathesis was present, and quinine when a history of malaria was obtainable, but the results in all such instances were likewise unconvincing.

A word regarding the use of opium and its alkaloids. It is the favorite drug to-day, as it has been heretofore. That its reputation of possessing curative influences is grossly exaggerated becomes apparent to anybody who watches his cases closely. The indiscriminate employment of the drug without limitation is more, it seems to me, a matter of custom and tradition, than one of therapeutics. As a reconstructive or specific agent, its usefulness is very questionable, but that it has some claim to merit as a palliative measure cannot be gainsaid. If improvement follow its employment, it becomes very soon apparent, otherwise its use should be discontinued. While it may diminish the secretion of urine, it diminishes, coincidentally all the secretions, and thereby gives rise to a general depreciation of the physiological functions, producing a condition which, if allowed to continue uninterruptedly, will surely entail more serious consequences than

the original morbid state would, uninfluenced by opium. I now employ this drug, in cases accompanied by a train of nervous phenomena, such as localized pains associated with polyuria, and in certain grave cases only when diet has no effect in checking the progress of the disease. I have learned from experience that opium has no effect on the morbid condition as such, but merely ameliorates symptoms, just as it acts in many other diseases.

This paper very properly ignores the consideration of many alleged cures and nostrums for diabetes, which have been in circulation from time to time, and whose exaggerated claims have not stood the test of experience or just criticism. We also note with keen disappointment the failure of modern therapeutics and bacteriology to establish a principle for the prevention and cure of the disease.

The treatment of diabetes may conveniently be considered under three divisions: *Prophylactic, Symptomatic, Dietetic.*

I. *Prophylactic Treatment.*—The maxim, "An ounce of prevention is worth a pound of cure," applies with double force here, for it is of more consequence to discover a case of beginning diabetes than to diagnosticate a number of advanced cases. To the former you can hold out hopes of a comparatively long life, but to the latter you only promise to prolong a life of suffering. Knowing that the disease cannot be radically cured, our duty is to discover it in its beginning with the hope that we may prevent its firm establishment, and to ward it off in those threatened subjects whose physiological demeanor indicates that they are candidates, so to speak, for the disease. Heredity, we know, plays an effective part in the etiology of this disease, and whenever this influence can be traced it becomes our duty to preach the lesson of abstemiousness. The children of diabetics, therefore, should, when they reach man's estate, restrict their diet in consideration of the family taint. As early as 1901 I advocated the necessity of systematic examination of the urine in all persons over thirty-five years of age, as a routine measure, even when in the apparent enjoyment of good health, just as the teeth are regularly submitted to the dentist's inspection (See MEDICAL RECORD, April 6, 1901), claiming that if this procedure would more generally obtain, many cases of threatened diabetes and nephritis could be disclosed in time to avert disaster.

The racial predisposition of Hebrews should be borne in mind, and the predisposition by reason of prolonged mental strain or a sedentary life, or exhausting intellectual occupations, should not be lost sight of. Another point of practical importance from a prophylactic standpoint is the close relation between diabetes and certain other morbid states, such as gout, obesity, hepatic congestion, affections of the nervous system, and arteriosclerosis. The occurrence of an excess of uric acid may be a forerunner of a confirmed diabetism. The urine of about one-third to one-fourth of all gouty subjects contains sugar in appreciable quantities. In obese subjects the enforcement of suitable exercise, general massage, and hydrotherapeutic measures is indicated. Subjects over thirty-five years of age in whom an enlarged liver is palpable, and who present, periodically, the following symptoms,—syndrome, icteric complexion, constipation, clay-colored stools, headaches due to the absorption of toxins from intestinal putrefaction, should always be under suspicion.

Finally, there appears to be a relationship between glycosuria and oxaluria. In some cases the latter was found to be the premonitory stage of the former, and due to over-indulgence in carbohydrates or nitrogenous food.

In passing, I wish to allude to a distinct pathologic entity which in a previous paper I styled "aglycosuric diabetes" (see MEDICAL RECORD, December 11, 1897), and which is of considerable prophylactic interest. It is a morbid state presenting a typical clinical picture of diabetes, with the exception that sugar is not excreted in the urine. This entity, for want of a better name, I might be permitted to designate, as "Paradiabetes." It is an anomaly of true diabetes and in all events the prediabetic stage, and is not of infrequent occurrence. The point of importance in connection therewith, is that this symptom-complex should be treated as a mild case of real diabetes. The treatment of the diabetic dyscrasia, irrespective of the subjective phenomena is important, for while we cannot cure diabetes, we can relieve suffering by surrounding the patient with every resource known to science, and thus postpone the final issue. A very important part, therefore, of the therapeusis, pertains to measures which do not concern drugs at all. Thus diabetics should seek mental, nervous, and physical rest whenever possible, and take exercise only under the supervision of a physician. The state of all the functions should be carefully watched, for we find in this constitutional affection, a diminution in the functionating power of all organs, especially in the eliminating organs. The skin, the bowels, and the kidneys, therefore, should receive more attention than is usually allotted to them.

When first discovered, a complete change of surroundings, such as a stay at a health resort, is desirable. Any place that offers natural advantages of climate, topography, and medicinal springs, and is equipped with hydrotherapeutic facilities, is to be preferred. It is much to be deplored that no such properly equipped resort is to be found on this side of the Atlantic. While we have many places that offer the natural advantages, they are not furnished with the appointments that are so necessary a part of them.

II. *Symptomatic Treatment.—Excessive hunger and thirst.* Diabetics will indulge their appetites despite the admonitions of the physician, and it therefore becomes a necessity to resort to some expedient to relieve them of their morbid desires, which are no guides as to the requirements for food.

The sensation of thirst does not entirely reside in the throat, but may be the expression of the needs of the body for water. In the case of diabetes, it is excited by the excess of sugar in the blood, which itself invokes a polyuria. Patients should be restrained from gratifying their appetites *ad libitum*, for overindulgence means overwork for kidneys and heart, which will sooner or later manifest itself in structural changes in these organs. The continual hunger is due to the fact that the ingested food is rapidly excreted without performing the functions usually ascribed to it. Among the measures that should be resorted to are the following: sucking small pieces of ice, drinking a mouthful of water at stated intervals in order to keep the parched mucous membrane of the mouth wet, drinking small quantities of water acidulated with lemon-juice or a little bitartrate of potassium. As a good summer beverage, lime juice and vichy without syrup may be advised; failing in these, total abstinence from carbohydrates for ten days, in conjunction with increasing doses of codein. Begin with one-third or one-fourth grain three times a day, increasing by one-third or one-fourth grain every third day, until two grains are taken three times daily, the third dose being given at bedtime to induce sleep. For the hol-

low feeling in the stomach due to the craving for food, asafœtida pills of one grain have been suggested, while for the intense craving for drink, saline injections into the rectum have been highly spoken of.

*Emaciation and weakness.* Emaciation accompanied by muscular weakness occurs at different periods of the disease, and in different degrees. Sometimes it is the first symptom that attracts the patient's attention to himself. It appears to correspond in severity to the degree of polyuria. This latter depends partially upon an overaction of the kidneys, which drains away the body fluids in general, and partially upon the fact that in a starch-prohibited diet, the oxygen of the system burns up its own fats. This emaciation is one of fats and muscle fiber, and when once begun is generally progressive, while its persistence is a fairly accurate gauge of the gravity of the cachexia. It is a fundamental principle of therapeutics that in all wasting diseases, the chief object of treatment should be to interrupt the waste of fat and to endeavor to replace the increment of loss. The success, therefore, of any method of treatment for the relief of the emaciation and weakness, would reasonably be measured by the skill displayed in preventing this loss of strength and flesh. The dietetic uses of fats for growth and nutrition are so well established that it would seem to be the part of wisdom to increase body weight by judiciously resorting to fats and oils, even at the expense of neglecting the glycosuria. Therefore, in the case of a rapily emaciating diabetic, the main indication is forced-feeding of fats and oils both in the form of natural foods and of artificial preparations.

Such pharmaceutical preparations as cod liver oil, and the fat emulsions that are on the market, serve useful purposes, and should be pushed to the limit of gastric toleration. Pure cream, whole milk, yolk of egg, butter, bone-marrow, edible oils, as well as fatty meats are all useful.

There is some difference of opinion regarding the limitations and advantages of forced-feeding of fats, objection having been raised on the ground that the acetone bodies found in didabetic urine are due to an excessive assimilation of fats, but practically such a claim has little value in the face of the ready methods in vogue for the detection of the urinary acetone bodies. The condition of the stomach and intestines, however, better enables us to estimate the quality of fats that may wisely be administered; for, directly a fatty diarrhea and other symptoms of intestinal disease make their appearance, we have a positive contraindication for their further use.

Of the articles enumerated, the most valuable as a reconstructive agency, and which at the same time is readily assimilated, is cod liver oil. It furnishes the wasting system with an amount of potential energy and heat that is equivalent to the consumption of large quantities of natural foods.

Accompanying the muscular weakness, we frequently find pain along the course of certain nerves, especially the sciatic nerve, or one of its branches. This pain is very obstinate in character, and is symmetrical in type. It is a true peripheral neuritis. I have found that opium alone gives little relief, but when combined with hyoscyamus as in the following formula: Extract of opium and extract of hyoscyamus, of each one-quarter grain three times a day, better results can be looked for. Rest in the inclined position is a valuable adjuvant.

*Glycosuria and polyuria.* As stated above, there are no specifics to ameliorate these symptoms. Taken by themselves, fortunately, they are never a menace to life. Of drugs, the one most resorted to is opium, or one of its preparations, in increasing doses, if occasion require; its mode of action is doubtful. The presumption is that it exercises a selective affinity for the vasomotor system, dries up the secretions, and allays irritability and pain. In regard to the method of administration, it should be borne in mind that if it is going to exert a beneficial influence on the cachexia, it will become apparent very soon, and before large doses are required. The notoriously large doses advocated by some authorities, in my experience, are positively harmful, just as they would be in any other disease. I never go above two grains of codein three or four times daily, as I have found that if the disease be at all amenable to this drug, it will announce itself before this maximum dose is reached. If no improvement follow such doses, its further administration should be discontinued. The same rule applies to opium and morphine, they should be given only in moderate doses, otherwise not at all.

In many cases the glycosuria has a tendency to spontaneous improvement, provided the system be not overloaded with carbohydrates. According to most observers, if a patient can tolerate 200 grams of carbohydrates in any form, daily, his glycosuria requires no further attention. Transient improvement can usually be hoped for, in the absence of intercurrent disease, unless the case be one of long standing, by means of a properly restricted diet, in conjunction with such aids as muscular exercise and suitable hygienic surroundings. In obese subjects over forty years of age, improvement of these symptoms is generally to be expected. Reference should be made here to the surprising fact that beneficial results have been observed by Mossé and Von Noorden to follow the use of measured quantities of carbohydrates, such as potatoes and oats. These investigators report that often the glycosuria and the polyuria would markedly abate after such a diet had been employed for a time and other therapeutic measures had failed.

*Skin affections.* The more important skin lesion is a dermatitis or eczema, accompanied by pruritus, about the female genitalia. Such pathological conditions as furuncle, carbuncle, and gangrene, do not properly belong within the scope of this article, being more relevant in a consideration of the surgical aspects of the disease.

It is known that subjects with saccharine blood, or blood conveying any other foreign substance, offer a lowered tissue-resistance, in consequence of which pus-generating organisms secure a readier entrance and meet a more favorable pabulum for proliferation; staphylococci, especially, are known to thrive well in a medium containing sugar. The direct and continual contact of saccharine urine, with the parts about the urethra may also cause pruritus, followed by solutions of continuity from scratching.

The natural inference as far as therapeusis is concerned is to remove the cause, which in the case of diabetes means to rid the urine of sugar. Of the multiplicity of local remedies suggested for the relief of diabetic pruritus, comment need not be made here of the inefficiency of most of them, and the positively injurious effects of some, such as carbolic acid, sublimate, and nitrate of silver solutions in any strength. Good effects from these irritating substances need not be looked for; what is indicated is a soothing and protective application. Seen at the beginning, a soothing lotion, such as "Liquor Burrowi," a saturated solution of boric acid, or the official lead and opium wash may give relief, provided dietetic measures to rid the urine of sugar supplement the local treatment. Seen later, when

the skin lesion is of a severe type, the following procedure will be found useful. Shave the affected parts carefully, cleanse with boric acid solution and dry, then apply over the affected area a coating of a 50 per cent. ichthyol collodion, and cover with lint or absorbent cotton, held in place with a T bandage. Repeat this whole procedure every third day, having previously removed the old collodion layer. This method has given me good results in a number of obstinate cases, and I have never seen it described elsewhere. The local application of adrenalin has given good results according to Meara. In extreme cases of *eczema intertrigo*, accompanied by great physical suffering and discomfort, with a pruritus so intense as to prevent sleep and which has defied all local and constitutional treatment, one measure is still left to us, another procedure that is not mentioned in the more familiar text-books, namely, catheterization of the bladder at regular intervals by night and day, with a view of preventing the affected genitalia from coming in contact with saccharine urine, with supplementary local and dietetic measures. This catheterization should be continued until the parts are restored to something like a healthy state. I recall one case of severe *eczema intertrigo* with such an agonizing itching that the patient was reduced to a state bordering on collapse. Nothing was of any avail, until the catheterization treatment was adopted.

*Diabetic coma.* Up to date, the treatment of this morbid state is based upon the presumption that the coma is brought on by an autointoxication, from abnormal acids, an acid toxicosis, so to speak. Whether we are on safe grounds in assuming that a hyperacidity of the blood is at the root of this concomitant of diabetes, is not yet certain, and consequently we are hardly justified in deducing from this unaccepted theory a rational principle of treatment. The bare fact that pathologic acids whose properties and occurrence are of doubtful origin, are found in the blood and urine of advanced diabetics, is not itself proof of a relation of cause and effect between the coma and these acids. We cannot logically accept the acid theory of coma until certain apparently contradictory events are reconciled. Firstly, it is known that alkali therapy in a developed case of coma, is rarely followed by recovery. Secondly, it is known that acid bodies are found in the urine in a number of other diseases that are never accompanied by coma. Thirdly, it is known that acid toxins may be present in quantities in the urine of diabetics without coma ever intervening. Fourthly, in a number of cases of diabetic coma none of the acid bodies were ever demonstrable. In other words, we can have the occurrence of diabetic coma minus the poisonous acids. Fifthly, in a suspected case of diabetic coma the urine itself rarely shows a hyperacidity. Experiments to ascertain the acidity, quantitatively, have been recorded. Although these features concerning the properties of the urinary acid toxins cannot satisfactorily be reconciled with the clinical findings, nevertheless, we have in the acetone bodies a working hypothesis, or starting-point, on which to build therapeutical data. Thus, we may claim that alkali-therapy, although of little value during the coma, has undoubtedly been of service prophylactically in the *precomatose* stage. Efforts, not without a measure of success, have been made along strictly scientific lines to trace the source of the acetone bodies to the fats taken as foods; some observers have even claimed to have succeeded in isolating the special variety of fat which predisposes to an acid intoxication. As a matter of fact, it is a very debatable question, whether the coma can be considered in the light of an acid intoxication. Nevertheless, in the absence of positive proof of the nature of the coma, whether due to toxic acids, gastrointestinal toxins, faulty tissue metabolism, or a mother substance of the acetone bodies, and further, in lieu of a better method of treatment, it would be the part of wisdom to direct our therapeutical efforts to the conditions as they occur and on an interpretation of the clinical manifestations.

The treatment of diabetic coma, therefore, should be considered under two divisions, firstly, that of the *precomatose stage,* and secondly, that of the *comatose stage.*

So far as the prophylaxis of coma is concerned, it is to be noted that the urine of diabetes should be regularly examined for the presence of the acetone bodies, and if present in increasing proportions, the diet should be relaxed. An exclusive diet of proteids and fats should be abandoned, while carbohydrates, such as potatoes, bread, milk, and alcoholic beverages, should be allowed in limited amounts. When the system no longer excretes these acids, a return to a rigid diet may be enforced. Should the trend of events indicate impending coma, that is, should acetone, diacetic acid, and $\beta$ oxybutyric acids, appear in the urine, and the patient complain of dizziness, nausea, or dyspnea, he should be at once put to bed, placed on a milk diet, protected against colds, fatigue, and nervous and gastric disturbances. Heroic alkali therapy is now employed. Bicarbonate of soda grs. xxx t.i.d. is to be administered, until the urine is markedly alkaline; brandy or whiskey is useful, and also vichy in large doses, such as ℥ viii every three hours; a hypodermic injection of natrobenzoate of caffeine or of camphor in ether should be given at once. All opium should be discontinued. Oxygen inhalations for the dyspnea should be given freely, and a high rectal enema of salt solution if the bowels have not been previously evacuated. I usually order a strong, quickly acting purgative, such as croton oil gtt. i, with a few drops of olive oil placed on the tongue; the heart's action should be watched.

A few drugs enjoy the reputation of being of great service, such as glycenic acid in ounce doses, to diminish the excretion of the acetone bodies. Others are urotropin, owing to the readiness with which it separates in the economy into formalin and ammonia, ammonium fluoride, calcium carbonate, etc., etc.

The treatment of the patient during the comatose state unfortunately is almost a hopeless task. In the despair of the situation almost any therapeutic measure, however heroic in its execution, would be pardonable. Blood-letting followed by an intravenous injection of an alkaline fluid into the blood current, should be first tried. At the same time, the hypodermatic injections of cardiac tonics, rapid and complete evacuation of the bowels by the aid of gtts. ii croton oil, with olive oil on the tongue, high rectal irrigation of salt water, and free inhalation of oxygen gas.

III. *Dietetic Treatment.*—Opinion is a unit in declaring that the keynote to the intelligent treatment of diabetes, is the question of diatetics; although there has not been any radical departure from existing methods of treatment, nevertheless, there has taken place somewhat of a general revision of existing dietetic principles, which have been followed by favorable results. The treatment of diabetes is no longer a matter of dietetic restriction, but one of dietetic regulation; it does not mean total abstinence from carbohydrates, but a control of carbohydrates; it means a diet to fit the individual, not a diet to fit the disease; it means that a sharp distinction must be made between the diabetic dyscrasia and confirmed diabetism.

The bad effects of a one-sided diet on the processes of digestion, absorption, and assimilation soon announce themselves in morbid phenomena due to disordered metabolism. The human economy resists the attempt to starve it of one of its essential food elements.

The nutritive requirements of the body for the proper maintenance of nutrition and of the vital forces cannot be ignored with immunity in health, much less in disease. Now, since each of the three great alimentary principles, proteids, fats, and starches, has a distinct physiological purpose, it stands to reason that a pathologic reaction must follow, either immediate or remove, when the economy is deprived of any of these principles. A rigid exclusion of sugars and starches in the treatment of diabetes is a thing of the past, nor do we often find it necessary to exclude them permanently from the menu of diabetics. On the contrary, we often substitute carbohydrates for fats in cases of marked acetonuria. It is in the dietetic treatment that individualization takes first rank. The individual necessities of each case should be ascertained by a careful consideration of the character and intensity of the disease, the patient's power of resistance, and his reaction; his physical propensities, whether lean or obese, and his idiosyncrasies of diet. Only after watching him closely can we arrive at conclusions as to what the best diet would be in the given case at the outset and during the course of the disease, for the diet must necessarily change to meet the exigencies of the disease. Nevertheless, there are some types of the disease which must be met at first by a strict exclusion of carbohydrates, at least temporarily. Fortunately, this dictum does not apply to the majority of diabetics.

Recently efforts have been made, based on chemical experiments, to estimate the heat or fuel values of the three groups of food-stuffs, proteids, fats, and starches, and from these deductions to calculate mathematically the nutritive necessities of man in health and in disease. As a result of these scientific experiments, we have an accumulation of statistical tables exhibiting the fuel values or potential energies in terms of "calories" of various foods. One table exhibits in parallel columns the percentage composition of various articles of food and the resulting potential energies also in terms of calories. Another table indicates the number of calories necessary to maintain health in subjects of different ages and engaged in different pursuits. These tables have been employed by numerous investigators as a means of ascertaining exactly how much of proteids, fats, and carbohydrates are necessary to repair the losses and wastes of the body in disease and the requirements in health. But it was soon discovered that, although these theoretical computations were inspired in a scientific spirit, they could not have anything more than an empirical value in actual practice, for the reason that the human machine refused to be governed by laboratory methods, and that something more than weights and measures were needed to decide the question of heat equivalents in foods. I have had some experience in the "caloric method" of feeding in diabetes, and am of the opinion that these empirical measurements of food values sound well on paper, but that practical experience does not confirm the conclusions as to their reliability. For there are so many sources of error, and so many disturbing factors at work in the body which influence the final results, that the merit of the method cannot go unchallenged. Again, admitted that the caloric estimates be corrected, it does not necessarily follow that these numerical values will be developed in the body to their fullest extent and at the most appropriate time for utilization, nor is there any guarantee that these fixed calorie values will not be influenced by one of the many physiological operations of the human machine, many of which are as yet uninterpreted. Nature's laws cannot be goverened from the laboratory. Reasoning by analogy, the same view must be taken of the value of the various special diabetic diets that have been proposed from time to time, especially by German authorities, such as Ebstein's, Düring's, or Naunyn's diet, the skimmed milk diet, etc. A long experience has shown that the claims made for these dietaries have proven all but worthless. No one routine and fixed dietary can be universally employed for all cases promiscuously, irrespective of individual conditions.

In the dietetic treatment, our first aim should be to ascertain approximately the daily excretion of abnormal urinary ingredients, the acetone bodies in particular, also the amount of urea. This point determined, we are in a position to decide upon the character of the diet as indicated by the metabolic processes. Next, ascertain the patient's tolerance for carbohydrates. This point furnishes the clue as to the quantity and quality of the starches and sugars that can be allowed. This is accomplished relatively by exhibiting a known quantity of carbohydrates, such as four ounces of bread, which equals sixty-six grammes of sugar. One or two days later determine the amount of sugar excreted; the difference between the quantity administered and the quantity excreted corresponds relatively to the the carbohydrate capacity of the patient. Another method is to have the patient swallow 100 c.c. of glucose, dissolved in 500 c.c. water on an empty stomach. Following this step, there are two possibilities brought to light. Either it is found that the subject has no tolerance for sugar or a mild tolerance for sugar; either of which conditions determines the quantity of sugars and starches that may be allowed. We have now arrived at a stage when we can rationally decide upon the dietary for our patient. We thus have two classes of cases. One set of cases who can dispose of a given quantity of starches, and another set that has no power of assimilation for starches.

Cases belonging to the first group can be much benefited by a judiciously selected dietary. Their urine should be regularly examined for urea and glucose. In this group of cases will be found diabetics who look well nourished and present few subjective symptoms. Such patients should be allowed a few glasses each week of some wine, such as Burgundy, claret, Moselle, or Rhine, also ale in preference to beer, inasmuch as in the former the sugar has almost been entirely converted by fermentation into alcohol and carbonic acid. A few pieces of rye or wheat bread are also permissible. The use of flour other than wheat or rye, as gluten, I have abandoned, as I have little confidence in them on account of their uncertain composition, and if taken in large quantities they throw into the circulation more starch than would obtain by eating a few pieces of rye or wheat bread. The substitution of potatoes for wheat flour is in accordance with recent views, and good results are claimed for this practice. Potatoes contain a low percentage of starch in comparison to flour, and it is asserted that the potash salts in them exercise a beneficial influence on the progress of the diabetes. The eating of green vegetables, namely the ones growing above ground is to be encouraged. It is customary with me to insist on one starvation day in each month, on which carbohydrates are rigidly excluded, while a laxative mineral water is substituted on account of its eliminative effects. When a patient first presents himself for

treatment, and there are no urinary contraindications, I begin the management of the case by a rigid sugar-free diet of about ten days, then restore carbohydrates gradually to the limit of assimilation. A knowledge of the percentages of starches in the various articles of diet is essential in treating diabetics.

In the second group of cases belong the severe types of diabetes, those that are scarcely amenable to dietetic treatment, and that excrete glucose even on a starch-free diet. Here the question of diet depends on the physical conditions and age of the patient. Our chief aim should be to prevent systemic intoxication and to keep up the general health of the patient. His diet, if an old person, should not be too prohibitive, as in such cases the treatment becomes worse than the disease, even though such a diet has no effect in diminishing the glycosuria. Alcoholic stimulation in old persons is urgently needed, as there is practically no substitute for it in those subjects who have attacks of temporary weakness. I especially prefer cognac and brandy to whiskey and champagne. Alcohol is really a food for such patients and is also of service in helping to digest fats. It should be the golden rule in the dietetic treatment of diabetes that there is no advantage to be gained in causing the glycosuria to disappear, if it be accomplished at the expense of the general health of the patient. In any event, it should always be borne in mind that the long-continued use of an animal diet is a menace to the diabetic, and that a certain amount of carbohydrates, or rather carbon, is absolutely essential to life, and that, deprived continuously of it, the body must necessarily consume itself or starve in order to supply the missing unit. A potent factor is to watch the functions of the organs of digestion and assimilation. Unless the physiology of these organs be kept at the proper standard, treatment of any kind will prove ineffectual, while waste and loss of strength cannot be repaired, however much the patient be overfed.

When we consider how differently individuals react towards carbohydrates, we are reminded that possibly there exist two other unrecognized nutritional diseases analogous to diabetes, characterized by the presence in the urine of the products of faulty proteid and faulty fat assimilation and giving rise to distinct clinical pictures, and that, after all, the disease now known as diabetes is merely one phenomenon of a complex pathologic entity yet to be identified. Already we recognize albumosuria and lipuria. The methods of examining urine for the presence of the products of faulty fat and proteid assimilation are as yet too crude and impractical to be of service to thec linician, but when this difficulty has been removed it will not be long, I venture to predict, before the nature of glycosuria will be fully revealed, and then possibly a new disease will be added to our nosology.

1309 Madison Avenue.

## CONGENITAL UMBILICAL HERNIA.

By CHARLES GREENE CUMSTON, M.D.,

BOSTON, MASS.

A CONGENITAL umbilical hernia is a tumor of variable size, containing one or several abdominal viscera, seated at the umbilicus and existing in children at the time of birth. Of the peri-umbilical hernia I shall have nothing to say, because the congenital type only arises through the umbilical ring, while the peri-umbilical form only occurs in the adult. Congenital umbilical hernia does not always have the same origin; some contain viscera, which have never been enclosed within the abdominal cavity, while in other cases the viscera forming the contents, after having been seated normally within the abdomen, protrude during the last few months of intrauterine life, or during labor. The former are not hernias properly speaking, because the word hernia means the exit from the abdominal cavity and what has never been contained therein can naturally never come out, consequently, it is rather more of a congenital malformation and not a hernia, properly speaking.

Gosselin, in his "Leçons sur les hernies abdominales" published in 1865, divided umbilical hernia into three types as follows: (1) very large hernia containing the liver and the larger part of the intestine, with absence of a considerable portion of the abdominal wall; (2) hernia of medium size seated at the base of the cord and having for contents the liver and intestine, or the liver or the intestine alone, but which cannot be reduced: (3) hernia the size of a small nut to that of a crab apple, round and transparent, situated at the base of the cord and reducible. This classification appears to me somewhat arbitrary and would be better designated as embryonal hernia, which corresponds to Gosselin's first group, and fetal hernia which develop after the completion of the third month of intrauterine life. In embryonal umbilical hernia three varieties may be distinguished. The first, which may be termed umbilical eventration, is characterized by an arrest of development of the abdominal walls, or a defect in the union of the walls. Such cases present large irreducible hernia, with the viscera sometimes only covered by a thin membrane in direct continuation with the envelopes of the cord, while at other times they are free in the amniotic fluid. The defective union of the abdominal wall may be more or less extensive. This first variety of hernia consequently offers most variable sizes, according to the extent of the arrest of development, as well as to the extent of the lack in union of the walls.

The contents vary from a single intestinal coil to nearly the entire intestine with its adnexa. The heart has occasionally been found as part of the contents, the liver is almost always present and it may alone form the tumor, and this leads me to remark that the umbilical vein, by going into the longitudinal hepatic fissure, forms a cord which fixes the organ to the ring and explains the formation of this hernial contents. The membrane forming the sac, which may rupture during intrauterine life is, I believe, generally considered as a prolongation of Rathke's primary membrane or the membrane reuniens.

The adhesions uniting the sac to the viscera appear generally due to agglutination and do not appear to be of an inflammatory nature.

The second variety is the diverticular umbilical hernia due to the persistency of the omphalomesenteric duct, which opens into the intestine by an orifice commonly termed the intestinal umbilicus. Obliteration of this orifice commences after birth and is complete from the thirty-fifth to the fortieth day, while the omphalomesenteric duct becomes atrophied and detached from the intestine at about the tenth week. In those cases where this duct persists it may lead to the formation of a diverticular hernia, but it is most infrequently for the diverticulum alone to form the hernia and, under these circumstances, it usually passes by unnoticed. It is consequently probable that occasionally it is included in the ligature of the cord and gives rise to intestinal fistula. It may, however, happen that the obliteration, which commences at its intraabdominal end, has taken place and then a small fistulous tract results, ending in a cul-de-sac, instead of the formation of an abdominal anus. It has been pointed out by Duplay that a diverticular hernia is occasionally present simultaneously with a

stricture or complete occlusion of the intestine and, under these circumstances, if the point of occlusion is situated below the entrance of the diverticulum, a thickening of the cord is met with, while gurgling produced upon pressure of the cord at its base is associated with symptoms of strangulation. These diverticulæ vary in caliber, while their length may be from five to ten centimeters, or even more.

In those cases where they develop into a hernia, a hernial sac is wanting and the diverticulum is adherent to the base of the cord, or at the internal aspect of the amniotic prolongation, thus rendering the rupture irreducible. It is most infrequent for the diverticulum to alone form the entire tumor and cases of this type reported in literature are few in number; usually it is accompanied by the presence of intestinal coils.

The third variety of embryonal hernia may be termed hernia of the vitellin loop. It is characterized by the presence of the intestinal loop united to the omphalomesenteric duct at the base of the cord and which, instead of little by little entering into the abdominal cavity, has remained adherent to the umbilicus. The remains of the duct may be found on this loop of intestine.

There now comes up for our consideration the congenital umbilical hernia, which develops after the formation of the umbilicus, during the fetal period, and which has been called fetal hernia in opposition to embryonal hernia. Here one is dealing with a true hernia, because the viscera make their exit from the abdominal cavity by way of the umbilicus, resulting in the formation of a sac lined with peritoneum. The size of these hernias is extremely variable, from that of a walnut to the size of a fetal head at term. The contents may consist of the large or small intestine or both, as well as the liver, etc.

In very large hernias it rarely happens that the fetus is born with the hernial coverings intact, because they are usually ruptured during labor, or even pregnancy, so that the intestine floats freely in the amniotic fluid. Two membranes may be distinguished over the portion of the dilated cord, namely, an external and an internal membrane, the nature of which I shall discuss when speaking of the etiology. The external integument is formed by the dilated umbilical cord and is represented by the amniotic membrane which on the one hand joins the skin of the abdomen and, on the other, continues directly on to the cord, forming its sheath. The internal lining of the sac represents the hernial sac properly speaking. Both membranes are united to each other by a layer of connective tissue which frequently takes on a gelatinous structure, similar to that bearing Wharton's name. Occasionally there are other intermediary layers, although in a varying degree of development, such as the abdominal fascia or muscles.

In the larger number of cases the sac is transparent, so that one can see through its walls and observe the coils of intestine and the meconium that they contain. In those cases which have not ended in death, this transparency becomes gradually attenuated and ends by disappearing.

The union of the sheath of the cord with the abdominal skin usually offers a distinct line of demarcation, but occasionally it may be irregularly indented, that is to say that at certain points the skin sends out prolongations on the sheath of the cord. Sometimes quite a large reddish fold will be noticed at the junction of the skin with the amniotic membrane, as was pointed out some years ago by Parmenter. Ahlfeld believes that the distinct limits are more frequently met with while the indented border is rarer and accompanies a vesical fissure. He injected a fetus by the aorta and found that the red coloring extended as far as the border, but not into the envelopes of the hernia, and there was not the slightest trace of capillary injection. Generally speaking, the two umbilical arteries are situated outwardly and below, while the vein is usually found above. It not infrequently happens that they may be distinguished through the transparent covering of the hernia. They may occasionally entwine the tumor. Then again the two arteries may be found thrown to the side, while in others they may vary as to their number. Ahlfeld, after having examined eight cords in cases of funicular hernia, found only one artery and one vein in five, while in the three others there were two arteries and one vein, and Otto, who examined eight cords, found one artery others there were two arteries and one vein, and vein quite frequently become united at the apex of the tumor forming the cord, but the insertion of the cord does not always take place at the apex of the tumor. Usually the cord occupies one of the sides and, according to Cruveilhier, the insertion is found more frequently on the left. It often happens that in these cases the elements of the cord, arteries, and vein, are thrown to the same side instead of being dissociated. In cases of irreducible hernia the insertion preferably takes place at the apex of the tumor. In forty-five cases where the point of insertion of the cord was given, Buschan found the following: Thirteen times in the middle of the tumor, once on the right of the tumor, and twice on the left, on the anterior aspect of the tumor once and on its lower aspect twenty-eight times, to the left and below five times, and to the right and below three times. This same authority makes the remark that the cord is usually very short and Otto has described a case where it was completely wanting, while the hernial sac was directly adherent to the placenta. A similar case has been described by Thorner.

The viscera contained in the sac vary greatly, but, as I have pointed out, usually a coil of intestine, the liver, or the stomach, is to be found, the liver alone quite frequently. Then again all the organs belonging to the digestive apparatus may form the contents of these hernia. Chadwick has described several instances in which the heart and stomach formed part of the contents, while Masurel has reported an instance of hernia in a child who lived ninety-five hours which had as contents the omentum, the intestine from the duodenum to the sigmoid flexure, and also a kidney which had no ureter. The liver, spleen, bladder, and kidneys were normal, and he supposes that the organ which was found in the hernial sac was a supplementary kidney.

The smaller hernias usually contain only some coils of small intestine, and, occasionally, as has already been pointed out, the contents may be represented by an intestinal diverticulum alone. In twenty-three cases, Kraemer found the following organs in the hernial sac: intestines twenty-three times, liver twenty-two times, stomach ten times, spleen five times, and the heart twice. Thus it will be seen that out of these twenty-three cases the liver was found only once less than the intestine and the above-mentioned authority is of the opinion that this proportion is below the real truth. He even believes that generally speaking one is authorized to admit that in the majority of cases where the liver was absent in the hernia, it nevertheless formed part of the contents. Lindfors collected sixty-five cases of funicular hernia, which were submitted to treatment, and has given the following figures relative to the contents: liver eight times, liver and intestines five times, liver and omentum twice, the cecum twice, while the stomach, omen-

tum, intestinal coils, and transverse colon were each met with once. In one case the larger part of the abdominal viscera were present, while in another the contents consisted of the heart, stomach, and intestinal coils. In forty-five other cases coils of intestine were alone mentioned as forming the contents, or, on the other hand, the latter were not indicated.

Very frequently congenital umbilical hernia is accompanied with other congenital malformation, so much so that Hertzfeld found twelve out of sixteen instances presenting the following defects: In four there was a fissure of the palate, in five fissure of the bladder, in three a pubic fissure, four spina bifida, and in one a cerebral hernia. Beside these one may meet with malformation of the genital organs, deformities of the bones, contracture of the joints, malformation of the feet and hands, and cyphotic or scoliotic changes in the vertebral column.

According to Lindfors, out of a total of nineteen instances of congenital umbilical hernia, nine were cases of abortion, and out of these there were three which presented no other congenital malformation. The remaining six presented malformations of the genital organs.

Malposition of the viscera is frequent in congenital umbilical hernia; the stomach and spleen often are situated lower than normally, while the heart and lungs may be drawn into the hernia if the diaphragm is lowered.

The viscera are frequently hypertrophied, but usually it is the liver which is partially enlarged, or in entirety, and becomes adapted to the hernial sac, taking on an absolutely abnormal shape. In large umbilical hernia, the vertebral column, frequently becomes curved and, according to Ahlfeld, it is sufficiently marked for the lower part to come in very close proximity to the shoulders; the cyphosis is usually associated with lordosis.

The mesentery may be possessed of a greater length than normally. The increase in size of the viscera may be explained from the fact that the hernia, by allowing the abdominal cavity to empty itself partially of its organs, those which remain within have a tendency to become hypertrophied in order to fill up the space left by those which have made their exit, and are consequently exposed to displacement. The mesentery becomes longer, due to the traction upon it by the intestine contained within the hernia, and it has been upheld that this exaggerated length has been the cause of the hernia, while in reality this would simply appear to be a secondary phenomenon.

I have pointed out that malformations of the genital organs are frequent, consisting principally of a double uterus or vagina, epispadias, a bifid penis or clitoris, etc., accompanied by pubic fissure and exstrophy of the bladder. Ahlfeld gives the following explanation: If the vitelline cord drags the intestine towards the lower part of the abdomen and retains it outside, a diastasis of the lower half of the abdominal wall will result; if the traction continues, the intestine crowded down towards the symphysis pubis pushes the allantoid before it and with it prevents the union of the structures coming from each side, which should unite in the median line. In this way the lower part of the abdomen and the symphysis remain with a fissure and, on account of the latter, those organs situated on each side of the symphysis and which, by their union should form the external genital organs, do not meet. The allantoid forms a large bladder, because it is not limited in front by the abdominal walls and remains perfectly free in every direction excepting posteriorly. Since it cannot form an excretory canal below, it becomes filled with urine and finally ruptures, and consequently the anterior wall thus disappears while the posterior wall alone exists and becomes covered with mucosa. On the other hand, de Quatrefages insists upon the part played by adhesions in explaining the formation of exstrophy of the bladder, because the former prevent the closing of the abdomen and the union of the pubic bone. He points out that the internal organs, arrested in their development, will remain outside, while the fissures, which primarily were normal, will persist and new ones may even form during this process and the formative force, being overcome by these different causes, will leave various organs incompletely developed, or, on the other hand, will either unite or bind together certain parts which Nature had destined to be separate.

In these cases of congenital umbilical hernia malformations of the intestines, such as absence of the anus or rectum, stricture of some portion of the intentine or its occlusion, have been frequently found. This has been explained as follows: At the commencement of the second month the lower half of the intestine forms a straight line extending from the lower end of the vertebral column to the upper part of the coil. This portion merely undergoes a slight lengthening during the following weeks. The descending part of the large intestine, by a slight curve forms the transversal portion which goes out directly by the abdominal cleft. As yet there is no ascending colon, while on the other hand the small intestine increases in length very rapidly. One can thus see that a traction produced by the omphalomesenteric canal can only result, as far as the small intestine is concerned, in an exit of other intestinal coils through the abdominal cleft, while the large intestine is exposed for this very reason to many changes, either in its point of attachment, or in its lumen. If the traction has occurred at a time when the lower end of the digestive tract is still closed, it happens that from the traction, the rectum is so much pulled upon upwardly that its lower end cannot take part in the formation of the anus. If the traction on the rectum continues at a later date a stricture in its lumen may take place from this same cause, while actual contact of its walls may bring about an obliteration and thus may be explained the various cases of stenosis of the lower parts of the intestinal canal.

Congenital umbilical hernia is relatively rare; Thudicum believes that it occurs once out of every two thousand births, while, according to Lindfors, it was encountered once out of five thousand, one hundred and eighty-four in a series of twenty thousand, seven hundred and thirty-five births occurring at the maternity hospital of Munich. At the lying-in-department of the Charité Hospital at Paris 3,043 births occurring between 1886 and 1894 showed no instance of congenital umbilical hernia. The question as to whether or not the sex has any influence on this malformation is a difficult mater to solve, but it may be said that out of the thirty-seven cases collected by Lindfors there were twenty-two boys and fifteen girls, while Buschan, out of a total of sixty-nine cases, found forty-three boys and twenty-six girls. Children afflicted with very large eventrations are usually born dead at or before term. The cause of death is difficult to ascertain, but German authorities are of the opinion that anemia of the fetus is usually the cause, and I have pointed out that quite frequently one of the umbilical arteries is missing, or they may be only slightly developed, and this is the cause of anemia.

Embryology teaches us that the blastoderm becomes divided into three layers from which the various organs of the embryo develop. These three layers are called respectively the external, middle, and internal. The medullary sulcus once formed, the

middle layer of the blastoderm becomes divided into two plates, separated from each other by a cavity. These two plates become agglutinated, one with the external layer and the other with the internal layer, the first forms the musculo-cutaneous plate, or somatopleure, while the second forms the fibrointestinal plate, or splanchnopleure. After this the primary and unique abdominal sulcus becomes divided into two sulci, the interior of which becomes inlaid in the external one. The internal sulcus is the starting point of the digestive tract, while the external sulcus gives rise to the thoracic and abdominal wall.

These two sulci soon become transformed into two closed tubes from union of their walls, and, consequently, the umbilical opening is double, just like the two layers which give rise to it. The closure of the internal layer or splanchnopleure forms the intestinal umbilicus, while the closing of the external layer or somatopleure forms the cutaneous umbilicus.

From the formation of the two umbilici it results that those parts of the splanchnopleure and somatopleure which enter into the formation of the embryo become completely separated from those entering into the composition of the envelopes of the vitellin sac, and later from those which enter into the formation of the amnios.

The internal sulcus, the starting point of the digestive tract, is produced by the folding in of the splanchnopleuræ. The intestinal sulcus forms the middle region of the digestive tract; at its anterior and posterior part it is in communication with the two tubular cavities terminating in culs-de-sac; the anterior intestine or pharynx and the posterior intestine or rectum. The anterior intestine develops first, while the posterior only becomes formed much later. The walls of the splanchnopleure consequently are in direct continuation with those of the vitellin sac. This communication progressively decreases in size so that after a while it only forms a canal or omphalomesenteric duct and soon its obliteration becomes complete. The canal then becomes the vitellin membrane and the viteilin sac ceases to be in direct communication with the intestinal cavity. If the omphalomesenteric duct persists, Meckel's diverticulum is formed.

The somatopleure accompanies the splanchnopleure in its development and forms a tubular pocket. This pocket forms little by little and finally gives rise to the cutaneous umbilicus, a concentric opening in relation to the intestinal umbilicus. After it has become closed it extends in a sheath which contains the umbilical vesicle and the placental vessels, in other words the umbilical cord. After having formed this sheath it again becomes folded near the placenta in order to continue directly with the amnios.

The abdominal wall is in the first place formed by two superposed layers, the ectoderm and the somatopleure, and consists in a transparent membrane designated under the name of "membrane unissante" inférieure," somatic plate of Hertwig, or Rathke's membrane. Later on it becomes completed by the appearance of new elements coming from the somatopleure or the protovertebræ.

Having thus summed up briefly the embryology, we will now consider the formation of embryonal hernia. If the borders of the somatopleure do not reach the median line of the embryo on account of arrested development, it happens that the thoraco-abdominal cavity does not close in front and the viscera which should fill it, such as the heart, liver, spleen, stomach, and intestine are consequently placed outside of the body. This arrested development, which also arises in the amnios, gives rise to an excessive shortness of the umbilical cord, or it may be completely absent, and, as I shall show later on, this brevity of the cord has been considered as the cause of these malformations, when in reality it is simply the consequence.

In certain cases the cord is completely wanting and Geoffroy Saint-Hillaire thought that adhesions played a considerable part in the formation of monsters, inasmuch as the adhesions which united the embryo to the placenta prevented the closing of the thoraco-abdominal wall. These adhesions were produced by the effect of the contact of the viscera belonging in the thorax and abdomen with the placenta. If the somatopleura only becomes united above the umbilicus, the thoracic wall will be formed, while the abdominal wall will be wanting; the celosomia is consequently only abdominal, if the fold only forms below the umbilicus the thoracic wall will be wanting more or less, a condition which is met with in certain cases of cardiac ectopia.

The cutaneous umbilicus may consequently remain widely open when there is an arrest in development. It not infrequently happens that the somatopleure becomes completely formed, but retains its primary characters of a transparent membrane on account of a defective formation of either the cutaneous, muscular or bony elements. In this case the viscera are contained at the base of the cord, being covered by the membrana reuniens. This absence of permanent elements added to the primary abdominal wall is, generally speaking, only partial.

Another cause of embryonal hernia is a defective regression of the omphalomesenteric duct. At the commencement of the fourth week, the intestinal tube, which, up to that time, represents a nearly straight line, and still in communication with the umbilical vesicle by a wide canal, commences to form its first loop. The median part of the intestine where the omphalomesenteric duct is inserted, becomes placed outside of the abdominal sulcus at the time this loop forms and the lower part passes above the upper, so that the cecum becomes formed from the upper branch of this loop. On account of the increase in length of the intestines at both ends, the tube elongates rapidly, so that at about the eighth week five or six loops will be found situated outside of the abdominal cleft. Then at he level of the fetal end of the umbilical cord appears a swelling destined to contain the intestinal loops situated within it and outside of the abdominal cleft, which at this time is undergoing closing. This swelling disappears as soon as the intestine enters within the abdominal cavity at the beginning of the third month.

At this time the omphalomesenteric duct becomes detached and obliterated, and a small rudimentary débris of this duct is still found suspended to the small intestine, although the remainder of it has completely disappeared. Under normal conditions the omphalomesenteric duct gives way to the traction exercised from both sides upon it; it becomes thin and finally breaks. Now, if one is dealing with a very thick cord, it retains the intestine outside of the umbilicus beyond the normal time and an umbilical hernia forms. If the intestinal loops have already entered the abdominal cavity, without any separation of the duct having taken place as a consequence a diverticulum is formed.

We now come to the consideration of fetal hernia arising in an umbilicus already formed and possessed of a peritoneal sac. This type is produced by the same mechanism that arises in umbilical hernia of children and adults. The theory of arrested development for explaining the formation of congenital umbilical hernia in the embryonal period was given to the medical world by Meckel and has been generally admitted, but before this theory others had been promulgated, but need not detain us here to any

great extent. Oken admits that congenital umbilical hernia is not the result of a protrusion of the abdominal contents, but from an insufficient retreat of the intestinal loops primarily situated in the umbilical cord, and he believes to have found in their relaxation the cause by which the gut does not enter into the abdominal cavity. According to his way of thinking, a mother, weakened by disease, might transmit this weakness to the fetus, whose intestines would be lacking the necessary force to enter into the abdomen. Thudicum believed that this process arose from a relaxed mesentery, while Lassus thought it due to an increase in the size of the liver, but if this were the case the liver should be found enlarged in all anomalies of this kind, a thing which does not occur. According to the former authority, the various causes may become combined and the intestine, filled with meconium, can, by its weight prevent the occlusion of the abdominal integuments. Then again the position of the embryo may have a certain influence. According to Buschan there is no one exclusive cause. Ahlfeld long ago pointed out, in describing a large number of cases, that it was nearly always the same part of the intestine which was involved, and especially the lower part of the ileum, cecum, and ascending colon with the afferent portions of the mesentry.

Now, since embryology teaches that this very portion of the intestine is at a certain epoch of development situated outside of the abdominal cleft, and that it only enters into the abdominal cavity after atrophy of the omphalomesenteric duct has taken place, Ahlfeld thought that the patency of the intestinal canal with the umbilical vesicle beyond the normal time, gave rise to these malformations, and to give weight to this explanation he quoted cases in which the abnormal presence of the omphalomesenteric duct was noted. I have already pointed out that this persistency of the omphalomesenteric duct, in point of fact, is quite frequently the cause of embryonal umbilical hernia, but I believe that Ahlfeld is in error in believing that it is the only process arising in these malformations. Chadwick explains the formation of this hernia by a defective development of the abdominal wall, but only in a certain number of instances. He says, however, that if the size of the abdominal organs is too great to be easily surrounded by the abdominal walls at the time when the latter should normally close, the intraabdominal pressure will prevent the return within the abdomen of a certain number of intestinal coils which, up to that time, have remained within the cord.

We find another cause for the formation of hernia in the persistency of the umbilical vesicle which in these cases draws that part of the intestine to which it is attached out of the ring. Duplay some time ago remarked that the peritoneum develops like the abdominal walls and mentioned the importance of this fact, because every time that there is a defect, or better still, an arrested development of the abdominal wall, this arrest must be produced to the same extent in all the layers entering into the formation of these structures, exactly as if they were formed by a single layer. Consequently the membrane covering the protruding viscera cannot be the peritoneum in cases in which the process arises from an arrested development. The absence or the presence of peritoneum forming the sac of the congenital umbilical hernia will consequently allow one to establish the distinction existing between these two varieties of congenital umbilical hernia. Those arising during the embryonal period, whose immediate envelope is the primary membrane of Rathke, and those of the fetal period which develop when the ventral plates have become united to form the umbilicus, and consequently where the peritoneum should exist forming the hernial sac. The hernias of this latter variety must consequently form after the third month of intrauterine life. Lindfors does not acquiesce in this theory, and, according to him, the peritoneum always forms the sac of embryonal hernia, this being because he does not distinguish the lower uniting membrane of Rathke from the parietal peritoneum. This only amounts to a simple question of words.

Generally speaking, the diagnosis of congenital umbilical hernia is an easy matter, and naturally imposes itself upon one when in presence of eventrations or a very large hernia, and I have pointed out the external characters which this surgical malady presents. The transparency of the envelope greatly facilitates the diagnosis. The variation in the size of the tumor when the child cries or struggles is also a most important diagnostic element. But, although the diagnosis is generally easy, it may occasionally happen that the size of the hernia is so small that it is passed by unnoticed, and so great authorities as Sabatier and Dupuytren mention a certain number of cases in which a loop of intestine or a diverticulum was included in the ligature of the cord and, for this reason, it is always prudent not to apply the ligature too near the umbilicus. In point of fact, I would point out to obstetricians that it is always well to determine whether or not a hernia exists before tying the cord, and this is readily discovered if one seizes the base of the cord between two fingers and by pressure to ascertain whether or not any organ is found to enter into the abdominal cavity. Or again, in order to be still surer, one may wait for the child to cry, because, if the intestine should be adherent and cannot be reduced, a substance foreign to the elements of the cord may be felt between the fingers. In some cases the intestine or the diverticulum may extend quite a distance into the cord, and in 1850 Stanley described a case where the midwife, who, nevertheless, had ligated the cord quite a distance from the umbilicus, included the intestine in the ligature, so that a fecal fistula occurred on the fourth day and the child died a week later from this unfortunate occurrence.

The diagnosis of the elements forming the contents in congenital umbilical hernia may be most difficult or even impossible, but the transparency of the envelopes will frequently allow one to note de visu the organs contained in the sac, but for this it is necessary to see the child immediately after birth, because the envelopes become rapidly opaque. Percussion will allow one to differentiate the intestine from the liver, if the intestine alone forms the contents, while, when the liver is present, dullness will be elicited. If both organs form the contents dullness will be detected in certain points. According to Meckel, when the liver forms part of the contents, the hernia will take on a bluish red hue and, if it is compressed, the presence of a solid body will be discovered which prevents the apposition of the abdominal walls. Duplay pointed out that considerable importance must be attached to the insertion of the cord when one was desirous of ascertaining whether or not the liver formed part of the contents of hernias partially or completely reducible. In this case the cord will be found situated on the left side of the tumor, which will easily be discovered if one recalls the relationship of the umbilical vein with the liver. The differential diagnosis with urinary omphalocele must also be made. This latter process will be diagnosticated, because it is fluctuating, transparent, and seated at the base of the cord. In these cases, as there is frequently a defective formation of the urethra, it is accompanied by complete or incomplete retention of urine.

Thanks to the progress realized in the treatment of congenital umbilical hernia, the prognosis of this condition has become more favorable than it was a few years ago. Duplay estimated that the prognosis essentially differed according to the variety. Umbilical hernia arising during the fetal period is not serious, but the same cannot be said of the process when it occurs during the embryonal period. If they are of a medium size the prognosis is always very serious. However it is at the present time known that this gravity was greatly exaggerated by the older physicians. According to the mechanism by which spontaneous cure takes place, it may be concluded that the possibility of reduction is an indispensable condition. Irreducible hernia, on the contrary, is usually incurable. As Duplay has said, it is evident that the prognosis will vary with each type and that the presumption of the viability of newly born babes will be in inverse relation to the extent of the umbilical eventration and in direct relation to the duration of gestation.

In making the prognosis one should also take into consideration those malformations which so frequently co-exist with the umbilical process because the former may be such as to be incompatible with life.

As late as 1856 Lauth made the statement that hernias of the cord were almost always beyond the resources of surgery, and that only a palliative treatment would prolong the life for a few days in children born with this defect, although in times gone by there had been cases of spontaneous cure reported, although exceptionally, in instances where the hernia was of small size. In 1866, Duplay in the work already alluded to, says that he considers the active measures for the immediate reduction of the contents as defective, and that in many cases this brusque reduction would be impossible, for the simple reason that the abdominal cavity is not sufficiently large to contain the intestinal mass developing in the cord. For these reasons he is of the opinion that one should simply support the umbilical region with a bandage and by short maneuvers to facilitate the reduction of the contents by enlarging little by little the abdominal cavity. In 1877, Orliac insisted upon the importance of preventing the falling off of the cord as long as possible, in order to allow the abdominal cavity to undergo that development which is necessary in order to receive the viscera forming the contents of the sac, as well as to aid Nature's efforts in allowing the underlying granular membrane the time for forming. He also points out that this membrane is not alone a protection for the viscera, but that, under the influence of its retraction which later on takes place, the umbilical ring will decrease in dimensions. He concludes that if the hernia is reducible the surgeon should limit himself to favoring Nature's action, which, in many instances, will effect a cure. As an operative procedure he advises, after having incised the umbilical ring and reducing the intestinal mass, to unite the wound with sutures, or, better still, to simply ligature the walls of the hernia supported by appropriate dressings. According to his way of thinking, irreducible hernias containing the entire liver are incompatible with life. He also pretends that, if the hernia is somewhat large, reduction should not be tried, because Nature does not proceed in this way, and, on the other hand, since the abdominal cavity cannot receive the viscera, which have never been contained within it, one is liable to produce dyspnea, syncope, and the formation of hernia through other openings.

As may be seen, Orliac and the majority of other writers of his time were content, in the larger number of cases, to employ an expective treatment, which they considered more prudent. They were still under the influence of the opinion held before them by authorities such as Malgaigne, Albinus, Ruysch, Hager, and Soemmering, who considered this affection as incurable and did not proceed surgically according to the precepts of the illustrious Ambroise Paré.

The numerous reported instances of spontaneous cure in former times are, for the most part, only relative and should not be regarded as real cures merely because the child lived. The hernia was not cured and as far as the final result of the process of granulation is concerned, from the standpoint of the quality of the occlusion of the hernial orifice, especially in instances of somewhat large hernia, the records leave much to be desired. Generally there is an insufficiency of detail relative to the nature and degree of the cure. Whether or not the process simply consisted in a covering over of the hernia by skin with a reduction in its size, or whether it was a complete reduction with a permanent occlusion of the hernial orifice are facts which are not clearly shown in the reported cases. Fleischmann, however, expressly states that, after the cure of a case of hernia described by him, a large tumefaction existed, through which the intestinal coils could be felt so that the wearing of a bandage was absolutely necessary. The autopsy of children dying shortly after a so-called cure had been accomplished, showed that a marked disastasis of the recti muscles existed, and it is evident that a properly conducted operation would have favorably modified this condition of the abdominal walls. From what has been said, it is not a difficult matter to come to a conclusion relative to the efficacy of expectant treatment.

A number of methods have been proposed for the radical cure of congenital umbilical hernia, the first of which we will mention being that of Dohrn, whose technique is as follows: at the apex of the hernia, at a point where quite a large quantity of Wharton's jelly is to be found, he raised a portion of the amnios with rat-tooth forceps and cut it with small scissors. He then separated the amnios from the peritoneum as he approached the umbilicus, which was all the easier to accomplish from the fact that Wharton's jelly is more abundant between these two membranes. The vessels were ligated with catgut, and afterwards the intestine was reduced; then the peritoneal sac with its internal borders was united in a longitudinal direction at the level of the umbilical orifice was also sutured with catgut. That portion of the peritoneum situated above the ligature was then resected. After having freshened the borders of the abdominal integuments, they were united in a longitudinal direction, excepting at the lower angle, where the ligated vessels were lying. Olshausen circumscribed the hernial orifice by an oval incision made at a very short distance from the cutaneous borders. On the skin he isolated the amnios from the parietal peritoneum, and seizing the cutaneous borders with forceps he drew them towards the middle of the hernial orifice. The umbilical vessels were cut and ligated, the oval wound of the abdominal integuments was closed after reduction of the contents, with deep and superficial sutures. From this it will be seen that Olshausen only removed the external hernial envelope and sutured the abdominal integuments over the reduced peritoneal hernial sac. According to his way of thinking, the great advantage of this method is the preservation of the peritoneum, because, in cases where the wound might break down, an occurrence not infrequent, it would be sure to heal, by granulations which would form from the abdominal integuments and would soon fill up the space.

The technique followed by Carl Breus consists in reduction of the intestine, the opening and removal of the hernial sac, after a provisional occlusion of the hernial orifice, and ligature. After disinfection of the field of operation he endeavors to reduce the contents within the abdominal cavity by a slight, but increasing, pressure, proceeding from the apex of the hernia towards its base. When the reduction has been accomplished, he endeavors, either by palpation of the sac, or by utilizing its transparency, to assure himself that it is perfectly empty, and, in order to avoid protrusion of the reduced viscera, a clamp is placed on the skin surrounding the base of the sac. One must be careful that the borders of the hernial orifice are applied against each other by the clamp as accurately as possible. After thus having obtained a provisory occlusion, he advises opening the sac carefully in a longitudinal direction, commencing at the apex and extending to the base, in order to be able to assure oneself by a direct examination of its interior, that the reduction of the contents has been complete. When this is not the case, if, for example, a coil of intestine has remained in the sac, it must be reduced before proceeding. If adhesions exist, the simplest way is to incise the peritoneal sac at the point of adhesion, to isolate the amnios, and afterwards reduce the intestine with the adherent part of the sac. Once the reduction assured, the sac is removed and the ligatures are applied immediately below the clamp. The two ends of a long and strong silk ligature are threaded on two ordinary needles, the needles are introduced into the tissues at a distance of about one centimeter. The ligature is double, so as to be able to ligate the tissues under the clamp in three parts. If the hernial orifice is of large diameter, a larger number of ligatures will be required. After having carefully tied the ligatures, the clamp is removed and an antiseptic dressing applied.

The reproach that has been addressed to this method is the insufficiency of the occlusion and the slight solidity of the cicatrix, but experience has disproved this. The tissue of the stump which has been ligated becomes eliminated, granulations form, which favor a solid union of connective tissue between the integuments over the surface of elimination and the integuments having been brought together by sutures are held intimately approximated, thus preventing any gapping. This technique, however, presents one disadvantage, namely, that it requires more from the abdominal walls than suture after freshening. In those cases where, after reduction, the intraabdominal tension is somewhat increased, the clamps should, at least partially, include the abdominal skin in their grasp, because if they are merely applied on the peritoneal amniotic part, they would tear it. The tissues included between the bites of the forceps are lost, they undergo necrosis, because the ligatures are placed below the clamp.

Herniotomy, without opening the sac, first advised by J. L. Petit, was reinstated in 1874 by Colson. In reality, however, this procedure is merely Olshausen's extraperitoneal method. In cases where adhesions are extensive, particularly when the liver is adherent to the hernial sac, it perhaps may have some good points, but nevertheless the incision of the sac, followed by its extirpation, is certainly the only proper method to follow in these days of aseptic surgery. The hernial orifice is transformed into an abdominal wound. In his technique, Dorhn freshened the borders of the ring, but, under these circumstances, the closure of the latter by sutures left two depressions above and below on account of the oval shape of the ring and, in order to avoid this result, Berger proposed incising a small portion of the linea alba above and below the umbilicus. Le Dentu resected above and below the orifice, two small triangles with their base at the ring. By this device the wound is made an elongated oval and the operation is certainly more efficacious without being rendered more serious.

In order to assure a more perfect occlusion, or to modify the various manners of closing the operative wound, Geisel, Polaillon, and Reverdin sutured the ring and the neck of the sac simultaneously, while Sien was one of the first to advise the separate suture of the neck and the ring. Lawson Tait advised, by making an incision parallel to the walls, to make two flaps, one being formed by the fibrous layer adherent to the peritoneum and the other by the fibrous layer adherent to the skin, and these two surfaces were brought together with the hope of obtaining a solid cicatricial wall. Lucas-Championnière insists upon the necessity of doing away with the peritoneal infundibulum, like in any other hernia. He closes the sac by chain ligatures after having executed tractions on the neck so as to do away with all depression. The persistency of a cul-de-sac of the peritoneum is merely an opportunity given for the formation of a new hernia, and it is for this reason that he draws the neck of the sac out as far as possible and sutures the peritoneum as high up as can be accomplished. Wylie calls special attention to the necessity of exactly approximating the deep aponeurotic layer in order to avoid a recurrence, and the same may be said of the exact approximation of the peritoneum. However, the majority of operators seem to be entirely ignorant of the fact that the thick fascia which unites the recti and forms their sheath, composing the linea alba, is in reality the tendon of the abdominal muscles and it is this fascia and not the recti which gives the abdominal walls their resistance in the transversal direction. The recti are easily thrown outwards by any force tending to separate them. On the other hand, Condamin proposed opening the sheath of the recti at the same time that the umbilicus was resected, the technique being as follows: After isolating the sac the upper part is carefully seized with dissecting forceps, and the sac is drawn up away from the viscera, and then with the knife a small incision is made into it near the point of the forceps. The opening is then enlarged and, guiding the scissors on an index finger, introduced into the interior of the sac, it is opened up without any danger of wounding the contents. After reduction of the contents, the adhesions having been broken up if any exist, the borders are freshened, and to accomplish this the left index finger is introduced into the ring in order to destroy any adhesions which may be present. The finger may be retained in the abdomen and curved in such a way that the ring and the linea alba above and below it can be incised so as to have a musculo-aponeurotic opening. The union of these two sheaths should form, after closing, the abdominal cavity, a common sheath for the recti. Before closing the abdominal wall the peritoneum is sutured according to Doyen's method for intestinal suture. The second layer should include the recti and the aponeuroses; the posterior aponeurosis being always somewhat covered by the muscle, the needle should be inserted at quite a distance from the freshened borders in order to be sure of including it in the suture; the skin is closed with interrupted sutures of silver wire. The patient must naturally wear an abdominal belt in order to prevent any mishap from coughing, straining, etc. Later on, the originator of this technique introduced a slight change which he considered important. Instead of closing the peritoneum alone, he includes the deep layer of aponeurosis with a running suture, care being taken to make a good seroserous approximation. If this method is

followed, Condamin believes that the peritoneum does not tear and the occlusion is consequently more perfect. The second layer of sutures includes the anterior layer of aponeurosis and the recti, while the skin is closed as usual. Without doubt in this procedure the mechanical obliteration is more perfect than in the others, because the parts are united in three layers.

Quénu has described a technique which he calls the musculo-aponeurotic mattress and is quite similar to Condamin's method. After closing the peritoneum the posterior layer of aponeurosis is sutured and then a second layer of sutures unites the recti, while a third suture closes the superficial aponeurosis of these muscles.

Duplay prefers a through-and-through suture and, having employed it considerably, has no fault to find. After having resected the thin skin forming the umbilical cicatrix, he inserts through-and-through sutures, including the skin in cases where the hernia is small. When the hernia is of fairly large dimensions, he excises the umbilical ring and closes this with a through-and-through suture not including the skin, the latter being closed with a separate layer. Personally I am inclined to resect as little as possible in cases of large congenital eventrations, and if there is any difficulty in approximating the freshened borders of the wound one should not hesitate to resort to free lateral dissection to quite an extent, which will permit the sliding over of the musculocutaneous layers. If, later on, secondary herniæ arise where these dissections have taken place, they can always be attended to, but at birth the most urgent indication is to cover over the viscera, which are only protected by a layer of peritoneum and a badly defined granular layer, with a cutaneous or a musculocutaneous surface.

Dauriac's modified technique, published in 1894, is as follows: Only one-half of each muscle is incised and it is divided longitudinally into two equal bands. The external band of each muscle is destined to remain intact and to assure muscular continuity. The internal band is incised with a knife transversely, the incision being carried up to the vertical incision in each muscle. This forms two muscular flaps which are crossed and sutured, the upper left flap being united to the lower right one and reciprocally. When dealing with congenital umbilical hernia this authority prefers total crossing of the recti to that of partial crossing.

Such are the principal methods which have been advised for the treatment of congenital umbilical hernia. As to the method to employ for the radical cure, I do not believe that any one can be considered the best, and it is well to make a selection among the various techniques according to the given case. In reference to Mayo's method, which in the adult is, according to my way of thinking, superior to any other, I having done this operation eighteen times without recurence, it has been purposely not alluded to when discussing the radical cure of congenital hernia because it cannot be readily applied with any chance of success on account of the necessary resection of the tissues which it involves.

Generally speaking, simple laparotomy with extirpation of the sac and suture of the freshened borders of the wound will be sufficient in a large majority of cases. As to the use of several layers of buried sutures, I can say from practical experience that, although they may be practised successfully in the adult, they are far from being easy in newly born children.

The question now arises as to when a congenital umbilical hernia should be operated on and, in reply to this, I would say that it should be done as soon as possible after birth, because dessiccation of the sac will soon become the starting point of inflammatory attacks in the viscera. If the operation is carried out carefully and without undue loss of time, babies will stand the operative shock and anesthesia well.

## SIXTY CASES OF GENERAL PARESIS—A CLINICAL STUDY.

By EDWARD LIVINGSTON HUNT, M.D.,

NEW YORK.

I have compiled a few statistics in regard to some cases of general paresis, which have presented themselves in the last seven years at Dr. Starr's Clinic—the Vanderbilt—in the College of Physicians and Surgeons, New York, and I have in several instances compared the statistics with those compiled by Drs. Serge Soukhanoff and Pierre Gaunouchkine from some 500 cases, which, during the years 1898-1905, atended the Psychiatric clinic of the University of Moscow.

The cases number sixty, and all are males; they do not comprise the entire number of cases of paresis appearing at the Vanderbilt Clinic during that time, but a very large proportion. I have selected those regarding which the records were most complete, and those in which comparisons could be most easily made with the cases from the Moscow Clinic.

A very large number of the sixty were fairly well to do, and either had a trade or had followed some calling in life. There was a printer, two carpenters, two plasterers, three seamen, a packer, two shoemakers, a caulker, a truckman, a painter, two tailors, a cook, three agents, three clerks, a machinist, and so on through the list. There were but three laborers, and none of the sixty represented the lowest strata of society, as so often does the average dispensary patient. The cases from the Russian clinic were also of the better class. They comprised merchants, accountants, those engaged in "intelligent" occupations, dealers, farmers, and servants. The farmers sent the smallest contribution; the mechanics the largest.

The proportion of married to single was large, in each clinic about two to one. The exact table is as follows:

| | Moscow Clinic. | Vanderbilt Clinic. |
|---|---|---|
| Married | 79.19 per cent. | 67.85 per cent. |
| Single | 19.01 | 32.14 |

Nearly every one of our cases was far advanced at the time of admission; as was shown by the well marked tremor of both lingual and facial muscles, and by the pronounced mental symptoms. The tremor was present in 75 per cent., the mental symptoms in 80 per cent. And again was the advanced stage of the disease illustrated by the length of time in which the patient had been complaining. Of forty-two patients just 50 per cent. had been complaining for one year or longer. And 33 1-3 per cent. had complained for at least three months. Only two had felt badly for less than a month.

I have arranged a table comparing the ages of the cases at the two clinics.

| Age. | Moscow Clinic. | Vanderbilt Clinic |
|---|---|---|
| At 20 | 0.60 per cent. | None. |
| 21-25 | 1.34 | 7.01 |
| 26-30 | 11.29 | 1.75 |
| 31-35 | 26.15 | 21.05 |
| 36-40 | 30.31 | 24.56 |
| 41-45 | 15.01 | 21.05 |
| 46-50 | 9.06 | 14.03 |
| 51-55 | 3.86 | 1.75 |
| 56-60 | 1.93 | 5.26 |
| Above 60 | 0.45 | 3.50 |

And I have also arranged a table of the American cases, showing them by decades.

| By Decades. | Number of Cases. | Per Cent |
|---|---|---|
| 20-29 | 5 | 8.7 |
| 30-39 | 19 | 33.33 |
| 40-49 | 22 | 38.5 |
| 50-59 | 9 | 15.7 |
| 60-69 | 2 | 3.5 |
| | 3 | |
| No record. | | |
| | 60 | |
| Between 35-45 years. | 35 | 61.40 |

It will be seen that the disease increases as the years advance, reaching its limit about forty-five, and then decreases in almost the same ratio. Over one-half of the entire number of our cases occurred between the ages of thirty-five and forty-five. It is unusual to find so large a proportion occurring in the fifth decade. And adding those cases in the fifth and sixth decades we find that over 18 per cent. of the cases occurred after the fiftieth year.

It is interesting to dwell a moment on the comparison of the age figures in the two clinics. The Moscow Clinic had cases at twenty and younger; the Vanderbilt had none before twenty-one. On the other hand as a balance to this the percentage of cases in the Moscow Clinic above sixty was less than one-half of one per cent., whereas the percentage in the Vanderbilt Clinic was three and one-half. The years in which the greatest number of cases occurred are identical in the two clinics—thirty-six to forty; in the Moscow Clinic there was a larger number occurring just before thirty-six, rather than just after forty; whereas in the Vanderbilt Clinic the percentage was the same. The Vanderbilt Clinic had a remarkably low percentage between twenty-six and thirty. The number fell off in the Moscow Clinic very greatly after fifty. In general one can say that in both clinics the greatest number of cases occurred before forty-one, whereas after forty-one the New York Clinic recorded more cases. The exact percentages are as follows:

| | Moscow Clinic | Vanderbilt Clinic |
|---|---|---|
| Up to 41 | 69.69 | 54.37 |
| After 41 | 30.31 | 45.63 |

The youngest patient of all was twenty-one; the case was typical in every respect. It was of the tabetic type. The patient first presented himself at the eye clinic, complaining of impairment of eyesight. The opthalmoscope revealed a well advanced stage of optic nerve atrophy, and the patient soon displayed a condition of marked mental hebetude. This young man had all the cardinal symptoms—the Argyle-Robertson pupils, the lost knee jerks, the tremor of the face and tongue, the paretic speech and handwriting and the mental symptoms.

The oldest patient was sixty-five; the case was of the ataxic-paraplegic type, with marked tremor and mental symptoms—delusions, hallucinations, and loss of memory.

The records of the Moscow Clinic show that the greatest number of cases occur in the years thirty-one to thirty-five; their youngest case was nineteen; there is mention of one of sixteen, but it is a girl, and I have not taken the female cases at all into consideration.

The facts elicited in regard to the knee jerk are as follows:

In one-half of the cases the knee jerk was exaggerated. This is also true of the Moscow Clinic. The following table of comparisons arranged by percentages will best show the records of the two clinics:

Table of Knee Jerks.

| | Moscow Clinic | Vanderbilt Clinic |
|---|---|---|
| Exaggerated | 50.57 | 53.57 |
| Diminished | 9.09 | 3.57 |
| Abolished | 19.89 | 30.35 |
| Normal | 12.31 | 1.78 |

The following represents in numbers the quality of the knee jerk as found in each of the cases at the Vanderbilt Clinic: The knee jerk was normal in one case, diminished in two, exaggerated in thirty, absent in seventeen, lively or active in six, no record in four.

It is worthy of note that in these sixty cases the knee jerk was normal in but one. In the Moscow Clinic the proportion of the normal knee reflex was considerably greater.

In the Vanderbilt Clinic cases the pupils were normal in eleven cases, that is 18.4 per cent.; whereas the typical Argyle-Robertson pupil was found in twenty-seven cases. If we except the eight cases in which the record of the pupil was incomplete or lacking, there remains a total of fifty-two cases. Of these twenty-seven give the Argyle-Robertson pupil, that is exactly 52 per cent. There were in addition ten cases recorded as displaying sluggish pupils. Probably more than half of these were very sluggish and therefore almost Argyle-Robertson, so that this type of pupils was fairly constant, occurring in much more than one-half of the cases.

Table of Pupils.

| Pupils re-acted | Moscow Clinic | Vanderbilt Clinic |
|---|---|---|
| badly ("mal") | 82.05 | 71.15 |
| or not at all. | | |
| Pupils re-acted | 17.95 | 28.84 |

Here I have been obliged to adopt the wording of the Russians.

The pupil records of the Vanderbilt Clinic are as follows: Normal in eleven, simply unequal in four, sluggish in ten, Argyle-Robertson in twenty-seven, there was no record in eight.

It is to be regretted that an examination of the fundus of the eye was not made in every case. As it is, I find that in six of the cases there was present a well-marked degree of optic nerve atrophy, and in two more the eyesight was very bad or failing. In these eight cases, in which there was an involvement of the optic nerve, an admitted specific history was present in but one, whereas such a history was denied in four and there was no record in three. The ages of the eight cases were taken from every decade.

The tremor was present in a large proportion of the cases—just 76.8 per cent.; this tremor invariably meant a tremor of the facial and lingual muscles. It was absent in one, present in forty-six, and there was no record in thirteen.

Of the thirty-four cases in which was present a record of the speech, 56 per cent. displayed the typical paretic speech. Only one case was normal.

The most common mental symptom complained of was loss of memory. Out of forty-eight cases twenty-seven displayed a very bad memory or a complete loss of memory. This is almost 60 per cent. Of these forty-eight twenty-seven displayed loss of memory, six mental hebetude, four were excited and irregular, five were peculiar, and only eight had delusions and hallucinations.

Mental symptoms were—absent in six and present in forty-eight; there was no record in six.

The records regarding the presence or absence of syphilis are not very complete, and we cannot deduce much from them. This may be due to the foreign birth of many of the patients, or to their ignorance, or to their unwillingness to comprehend the question. Of the cases recorded syphilis was admitted in 59.3 per cent. and denied in 40.6 per cent.

Table of Syphilitic Infection.

| | Moscow Clinic | Vanderbilt Clinic |
|---|---|---|
| Admitted | 61.54 per cent. | 59.37 per cent. |
| Denied | 19 61 | 40.62 |

In those cases in which was kept a record of the time of appearance of the disease after the period of infection it was found that the time varied from five to eighteen years. It was usual, however, to have the paresis develop about fifteen years after the in-

itial lesion. In the Moscow Clinic the period was shorter—six to ten years.

If now from these statistics we deduce a few conclusions and formulate them in a clinical form we should expect to get a composite picture of paresis that would be as follows: A man of about forty-five, fairly well to do, married, and with a trade, who has been perfectly well until within the last year or fifteen months. About that time he begins to feel nervous, weak and restless. This condition becomes worse, and when he presents himself to the physician he has the Argyle-Robertson pupil, a tremor of the facial and lingual muscles, and a paretic speech. The knee jerks are exaggerated and he has a distinct loss of memory. When questioned carefully he admits that some fifteen years ago he did have a chancre.

## THE HIGH FREQUENCY SPARK IN A XANTHOMA-LIKE DEGENERATION OF THE LIPS.

By CHARLES WARRENNE ALLEN, M.D.,

NEW YORK.

CONSULTING GENITOURINARY SURGEON TO THE CITY HOSPITAL; PROFESSOR OF SKIN DISEASES, N. Y. POST GRADUATE MEDICAL SCHOOL, ETC.

In 1896 Dr. J. A. Fordyce (*Journal of Cutaneous and Genitourinary Diseases*, November) called attention to a peculiar affection of the mucous membrane of the lips and oral cavity. The case described is illustrated by an excellent colored plate and photo-micrographs, to which I will refer instead of going into lengthy detail. The changes resulting in a yellowish white discoloration of the vermilion border were chiefly confined to the epithelial cells, the protoplasm having degenerated into a substance allied to, but not identical with, keratohyalin. The condition is quite common, but as it rarely gives rise to any inconvenience other than the peculiar appearance when the separate mustard-seed-sized lesions fuse into an almost solid patch, the physician is seldom called upon to treat it.

Till now this has been fortunate since no plan of treatment previously suggested has been efficacious. In Dr. Fordyce's case and others iodine applications were made without result. Curettage was not wholly successful, and had too glaring disadvantages. Dr. Fordyce's original paper needs one correction. In his closing sentence he says: "I report the affection as an example of a mucous-membrane change, which, while apparently not uncommon, has hitherto escaped observation." The word "report" is undoubtedly intended instead of "observation," since at the meeting at which the paper referred to was read I, along with others, spoke of having observed it many times before, and I had pointed it out to students prior to the report without being able to tell them its nature, nor what to do for it. I have since learned to regard it as of very frequent occurrence, and have seen the identical condition on the lips of the female pudenda. Now, while I have never had a patient consult me for this affection alone, I have repeatedly called the patient's attention to it when slight (and to be seen distinctly only when the lip is put upon the stretch). I have also asked them if they would not like to have it removed, when it has been pronounced—giving the appearance of an extremely anemic vermilion border, or suggesting xanthelasma. Until the high frequency methods came into vogue, as I say, there was no practical method of treatment known to me, and I rarely attempted anything. Several years ago I found in the high frequency spark the most practical and perhaps the least painful, prompt, and satisfactory method of removing disfiguring xanthoma tumors from the neighborhood of the eyes. Struck by the resemblance between the two conditions I began to treat these lip cases, and with very prompt and good results. In two of the patients there was coincident xanthoma of the lids, which I cured with the spark. One was also a subject of lues. Indeed most of the patients so far treated have been syphilitic, and in two I feel quite sure that the lip degenerative change began subsequent to their coming under mercurial treatment, but I do not wish to draw any conclusions from these facts. The condition undoubtedly exists in whole series of members of a family in which there is no lues, no ingestion of mercury, and no xanthelasma. In applying the high frequency spark I employ a static machine and a hyperstatic transformer, a large carbon electrode, a spark gap of two inches, and a contact spark of about an eighth of an inch, or one which will cause almost at once a marked whitening of the surrounding pink of the lip. Two or three sittings usually suffice and the pain is trifling.

## A CASE OF ACUTE INTERNAL HYDROCEPHALUS.*

By THEODORE DILLER, M.D.,

PITTSBURG, PA.

NEUROLOGIST TO THE ALLEGHENY GENERAL HOSPITAL; VISITING PHYSICIAN TO THE INSANE DEPARTMENT OF ST. FRANCIS HOSPITAL.

A girl, aged four years, was sent to me by Dr. Simpson, of Indiana, Pa., on May 27, 1904. She was the third child of healthy parents. Her birth was uneventful. Her brothers and sisters are all healthy. She developed normally, and was in perfect health up to one and a half years ago, *i. e.* up to the age of two and one-half years, when she became suddenly ill with a fever, which confined her to bed for a week. Recovery seemed perfect. Six months later (at the age of three) the eyes turned inward, first one and then the other. These internal squints grew more marked during the next six months, when the squint of the left eye became less pronounced than that of the right.

Five months before I saw her she had an attack which was characterized by high temperature, badly coated tongue, and suppression of urine and albuminuria, and which was thought to be an attack of Bright's disease. She did not make a good recovery. In March (two months before I saw her) she had vomiting attacks. She often screamed and jerked in her sleep; again she would sob and laugh alternately. For a time she was delirious—said dogs were after her, etc.

Early in April it was noted that she did not use the left hand as much as the right; and a couple of weeks later she began to drag the left foot. These palsies steadily increased; and in the meantime defects in articulation were noted.

When examined by me, the child was somewhat dull and irritable mentally. No alteration of sensation could be discovered. She had a marked internal squint in both eyes, more marked in the right than the left. She was able to walk alone, but there was marked spastic paralysis in left arm and leg. The left knee-jerk was greatly exaggerated. Ankle clonus and the Babinski toe reflex were present on the left side. There were beginning contractures in the left hand. An ophthalmoscopic examination

*A paper prepared for the annual meeting of the American Neurological Association, held in Philadelphia, June 1-3, 1905.

could not be made. Articulation was somewhat defective.

On November 2 (more than five months later) Dr. Simpson wrote me as follows: "When you last saw her she had an aggravated strabismus, and dragged her one toe when walking. Her condition rapidly grew worse. She had what was like an attack of indigestion, sick stomach, temperature of 102-3, obstinate bowels, etc., but was evidently more than that, for afterwards she became perfectly helpless, and has remained in that condition ever since—about fourteen weeks. She cannot turn in bed, or swallow solid food, or speak, or cry, except a slight whine. At times she moves her arms just enough to change their position. All the muscles in the legs are atrophied, more especially those of the calves of the legs, which are perfectly flat. The feet are drawn into the position of talipes equinus, and are nearly always rigid. The thenar and hypothenar eminence of her hands have disappeared, and her fingers are usually drawn tightly into the palms. However, on some visits, I find them relaxed and quite flaccid. She remains in the one position until changed, for she cannot turn in bed. She was quite emaciated, but has gained somewhat in flesh. Her pupils are equal. Pulse is about 100 and weak. Bowels and urine regular and involuntary. Temperature normal. She can take only liquid nourishment, and that in teaspoonful doses. Tactile and contact sense appear to be everywhere absent. When hungry, she attempts to cry, and will only take malted milk, and appears never to be satisfied. In swallowing, she has not the proper use of her tongue, for even in teaspoonful doses she will allow part of the liquid to run down over her mouth. She sees and hears, and will often answer direct questions by nod of her head. She is certainly the most helpless little creature I have ever treated. I will add that she suffers no pain; she lies quietly all the day or night in the one position. She can not or will not protrude her tongue."

On December 19 (six weeks later), Dr. Simpson wrote again: "Since I wrote you, she gradually became weaker, and her condition not changing materially until she finally died of exhaustion. I removed the brain and had a good look at it, but, owing to circumstances, I had to return it, so you will be minus a nice specimen. The condition was one of internal hydrocephalus. The sutures of the skull were not separated—I suppose for reason of the child's age, four and a half years. The cortex of the brain was almost smooth. The convolutions and fissures almost obliterated, and the brain itself giving one the impression that he held in his hand a bladder. Before I had the brain entirely removed, it accidently ruptured, and about a pint of clear fluid spurted out on the floor. I made an incision down through the brain substance and could readily see the distended ventricles. The two hemispheres appeared about equal in size. During life, I had often noticed the child's head, and at times thought I could detect some enlargement, especially in the temporal regions, but I was not positive of it. The skull cap was very thin, the saw going through it very rapidly."

It is likely that the fever from which the child suffered at the age of two and a half years was the first manifestation of an internal hydrocephalus, which more or less steadily progressed, and terminated the child's life two years later.

I am indebted to Dr. Simpson, whom I desire to thank for permission to record this interesting case, and for his excellent descriptive letters, which form the most important part of this contribution.

I may add my original diagnosis was poliencephalitis.

200 Ninth Street.

## A CASE OF ABDOMINAL PREGNANCY UNDIAGNOSED UNTIL AFTER OPERATION.*

By A. J. Ronginsky, M.D.,

New York.

Instructor in Diseases of Women at the New York Post Graduate Medical School; Attending Gynecologist to the Lebanon Hospital Dispensary.

The complete ignorance of the true pathological condition of the following case, although the woman had been attended by no less than fourteen physicians at one time or another, is certainly of interest to the profession at large.

Mrs. L., aged 39, Russian, always attended to her house work, married at the age of 21, gave birth to seven children, oldest 16 years, youngest 11 months. Labors normal. Had one miscarriage seven years ago, and was curetted for same at the Gouverneur Hospital. Her menstrual history was regular as to time, quality, and quantity. She never menstruated during lactation.

On June 10, 1904, she appeared at my office complaining of pain in the epigastric region, and slight vomiting. On examination, nothing objectively could be discovered, and I thought her indisposition to be due to an acute attack of indigestion. I prescribed the usual remedies. She called again the next day, slightly improved, but still had some pain in the epigastric region. Assuming that my diagnosis was correct, I continued the treatment on the same line. She felt greatly improved until June 14, when I was called to her house, she having had another attack of pain in the abdomen and some vomiting. On examination, I found her abdomen slightly distended, with tenderness in the epigastric region. Assuming that all her symptoms were due to constipation from which she had suffered for the past three days, I prescribed small doses of calomel to be followed by a saline. On calling the next morning I found her very much improved.

I next saw her on June 21. Her condition had undergone a great change. She was very anemic, her abdomen was markedly distended, she was more or less emaciated, telling me that she lost 9 pounds by actual weight. She presented a true clinical picture of one suffering from intestinal obstruction due to a malignant growth. Her condition rather alarmed me, and I advised that a consultant be called in, but she felt better the same afternoon.

I saw her again on June 25, and her condition instead of getting better, grew worse since my last visit. The distention was very marked, the emaciation more apparent. Some one advised her to see a local surgeon which she did on the previous day, but fainted in the doctor's office, and had to be brought home in a cab. The doctor called at her house a few hours later, and after examining her, prescribed digestive powders. Her general condition gradually grew worse and the obstruction became more marked. On July 1, I asked a prominent stomach specialist to see her with me, and after a careful examination he thought the patient suffering from a general neurosis of the intestinal canal, causing spasmodic contraction of the walls of the intestines from which resulted the pain and obstruction. He advised appropriate treatment, and the patient felt somewhat better for a few days, but on July 5, she again had an attack of pain in the ab-

*Read before the Eastern Medical Society.

domen which lasted for about two hours. I gave her a high rectal enema of ox gall and olive oil, which relieved her only slightly.

At this stage of her illness I confessed to her family that I was rather puzzled as to her condition. I advised that the same consultant see her again. We met on July 10, and after a thorough examination the doctor thought that she was probably suffering from a malignant growth of the cecum, but no mass could be felt. The same treatment was continued with the addition of a stomachic tonic.

The fact that the patient had lost 25 pounds by actual weight, that the obstruction was on the increase, and that she was severely anemic, made me think the diagnosis quite reasonable, and from now on I thought her condition to be hopeless, and tried to relieve her symptoms only. I saw her daily up to July 17.

During the week of the 17th, a local physician was called in to see her without my knowledge. Later I was informed that no diagnosis was established by the doctor, and he also treated her symptomatically only. The obstruction increased, the abdomen being so distended that the skin began to show signs of atrophy at some points. Not being able to make her comfortable at home, I advised her removal to a hospital, and on July 28 I had her admitted to one of our prominent hospitals. After being examined by the attending physician and surgeon, the gynecologist was called in to see her. A probable diagnosis of obstruction due to some growth was made and an exploratory laparotomy was advised. The hemoglobin was too low, so the operation was deferred for the present.

Her condition slightly improved during the next few days, and she was operated on August 6, and no sooner than the abdomen was opened, a fetus of about 3½ months appeared at the opening. The greater portion of the placenta was attached to the small intestines, also to the ovarian end of the tube. She died 3½ hours after the operation, not rallying from the profound shock which she went into the minute the abdomen was opened.

I am fully aware that at times a secondary abdominal pregnancy as the case here, may puzzle the most competent expert for a time, but for a pathological condition to deceive completely over a dozen physicians, some of whom are considered the most competent in their special fields, should not pass by unnoticed. Every one examined her gynecologically and to no one was the condition of the uterus suspicious. I will repeat that if ever I saw a case of chronic obstruction of the lower bowel, this certainly appeared to be one. At the latter stage of her illness her abdomen had to be supported, and to put it in her words, "Her belly was too large to be carried by her thin emaciated body."

---

**Important Differential Points in the Diagnosis of Sporadic Cretinism, Mongolism, Achondroplasia, and Rachitis.**—Charles Herrman defines the terms which he uses as follows: Rachitis here considered is the ordinary form so often seen in infants and children. Only the sporadic cretinism or infantile myxedema is here considered. By mongolism he refers to that form of congenital idiocy of unknown origin in which the patients show the Mongolian slant of the eyes. Achondroplasia is considered as it occurs in infants and children. The writer gives a comprehensive view of the e diseases, with their points of difference. Among the facts which he discusses are the following: A marked, persistent, subnormal temperature, which reacts immediately to thyroid treatment, is characteristic of sporadic cretinism. The temperature in mongolism is sometimes subnormal, but this is never so marked or persistent as it is in cretinism. Rachitis and chondrodystrophy, when uncomplicated, have a normal temperature. In cretinism, as against mongolism, the skin often has a characteristic myxedematous infiltration. In all of these conditions there is a delayed closure of the fontanels. In rachitis the head is large and square. In mongolism the head is brachycephalic. In cretinism the head is small, with no special characteristics. In chondrodystrophy the head is relatively large. In this affection also the end of the nose is bulbous. This is different from the condition of that feature in cretinism and mongolism. In cretinism the tongue is enlarged; this is not so in mongolism. In all of these affections the teeth appear late, but especially so in cretinism. In all of these conditions the extremities are shorter than in the normal. In cretinism the hand is flat and spade-like. In rachitis, when it is well marked, and especially in the second year, the hand is long and narrow, with the thumb flexed. In chondrodystrophy the hand is small and square. In mongolism the hand approaches more nearly to the normal. As to the mentality, the intelligence in rachitis is retarded only in so far as the children do not mingle with others early. In chondrodystrophy the intelligence is not markedly affected. Cretins when untreated are sluggish, apathetic, or idiotic. In mongolism there are all grades, from the mildest form of imbecility to complete idiocy. Treatment with thyroid extract is specific only in the cases of sporadic cretinism, although the other conditions may be somewhat improved by this medication.—*Archives of Pediatrics.*

**Biology of the Anaerobic Microorganisms.**—Giovanni Grixoni has carried out very extensive experiments with regard to the possibility of cultivating organisms that are usually anaerobic in the air. He gives us these conclusions: 1. Many anaerobic germs, the cause of grave infections in men and animals, may multiply and produce toxins in the presence of atmospheric air. 2. In order that these microbes, habitually toxic, may become virulent special conditions are necessary which are rarely found in nature. 3. If fragments of fresh organs, taken from healthy adult animals, be mixed in the substrata of cultures, as they decompose *in vitro* a rapid multiplication goes on in the air of the bacilli of tetanus, of malignant edema, etc. 4. Such germs increase in virulence by transplantation into fresh substrata. If left in the same medium they lose their toxic power. 5. Such germs lose their toxic power when cultivated for a long time in presence of oxygen in nutritive broth rich in ammonia. 6. By modifying the culture medium it is possible to make these anaerobic germs grow in the air. 7. These experiments give us much information as to the pathogenesis of several surgical diseases up to this time obscure.—*Giornale Medico del Regio Esercito.*

**A Study of the Physiological Biliary Flora.**—Andrea D'Ambrosio has made experiments to determine whether the bile normally contains any microorganisms. At the present day it has been determined that the bile is not bactericidal nor antiseptic in its action. The author made use of the bile of dogs, rabbits, and guinea pigs, after having fed them on appropriate food for several days. He did not use chloroform in any of the cases, nor any method of anesthesia. He obtained the following results: Of 45 animals used, only 19 showed microorganisms in the bile. In these cases the bile was found to be turbid and more dense than normal. In all cases of limpid bile no germs were found. He therefore supposes that the bile of the animals in which the germs were found was not in a strictly normal condition. The bile of the majority of normal animals is probably sterile. The microorganisms found were a form of diplococcus, which has been described by Escherich as micrococcus enteritidis; another corresponding in morphology to the bacillus subtilis, and, less frequently, still another similar to the last.—*Giornale Internazionale delle Scienze Mediche.*

## A SANE POLICY ON THE ISTHMUS.

AFTER making several false starts, those responsible for the construction of the Panama canal seem at last to have come to reason, and have determined to begin again and begin right. The makers of the canal started out with the brave resolution to dig, dig at once, and keep on digging until the canal was dug, the theory being that the way to do a thing is to do it. But theory and practice are not always compatible, unless the theory is sound. If the canal could be cut by machines of steel, whose only enemy is rust, and without the supervision of vulnerable man, the original plan of the canal diggers would have been admirable, and perhaps even the former commission of incompetents would ere this have been well along on the way to the completion of their task. But, like so many men of affairs, engineers, and army officers, they ignored the lessons of the past and refused to heed the warnings of the medical profession that the work of sanitation was the prime necessity, and should be the first to be undertaken. They professed to believe that the failure of De Lesseps was due to the wholesale stealing of his subordinates and failed to see that it was disease rather than graft that thwarted the efforts of the French. They made a concession to the demands of the medical profession in placing Col. Gorgas in charge of the sanitation of the Isthmus, but they saw to it that he was not a member of the commission, but rather a subordinate with little or no authority to carry out the indispensable measures of sanitary reform. The result is known. In spite of his best endeavors, hampered as they were by ignorant and unsympathetic members of the Canal Commission, malaria and the fear of yellow fever seized upon the officials and laborers, and the work came practically to a standstill almost before it was begun.

How long these more than useless commissioners would have gone on putting this murderous theory into practice no one can say, had not Dr. Reed been sent to the Isthmus on a non-medical mission. While there he carefully compounded a bomb which he exploded on his return to Washington, with the happy result of disrupting the old Canal Commission. We opine that the Washington authorities had a suspicion that he would cast a medical eye over the situation while in the Isthmus, otherwise the appointment of a physician to appraise the value of land, which was the ostensible purpose of the commission of which he was a member, would have been incongruous. Whether the indignation which the Washington authorities expressed at the premature publication of his report in a medical journal was real or feigned, the old Canal Commission was promptly dissolved and a new one appointed. The new commission, of which Mr. T. P. Shonts is chairman, is evidently of different stuff, for it is taking hold of the canal problem at the right end. It is now announced that the work of digging the canal is to stop while every effort is to be made to better the sanitary condition of the Isthmus.

An engineer, who returned recently with some members of the commission from Panama, has given out an interview in which he outlines the new plan of campaign. The work of excavation has stopped and that of sanitation is to be pushed along with the greatest possible speed and efficiency. Working stations exist at short intervals all along the line of the canal. At each of these, cottages will be built for the married employees and a hotel for the bachelors. Appropriations have been made for these buildings at seven stations. It is suggested also that the old army canteen be established at each of these work-towns, where the men can bowl, play billiards or cards, other than poker and pure gambling games, and get a glass of beer or light wine if they want it. But no liquor will be sold, nor will any saloons where it is to be had be allowed on the line of the Canal Zone. In addition to building decent quarters for the men, providing them with various forms of innocent entertainment, and improving the personal hygiene in other ways, the authorities are also prosecuting the the work of sanitation vigorously. War is being waged chiefly against the mosquito. In the country the tall grass is kept mowed down, the pools are repeatedly swept out, and all stagnant water is treated with oil. In Panama the streets are being paved, the pools in the still unpaved portion are repeatedly covered with oil, and twice a month every house in the city is thoroughly fumigated. These measures have borne fruit, for although there has been some yellow fever in Panama, the cases were few; but there can be no doubt there would have been an epidemic, with so much fresh material for the disease to feed upon, had it not been for the untiring efforts of the sanitary authorities.

If Col. Gorgas has accomplished so much while hampered by the hostility or imbecility of the old commission, there is every reason to believe that when his efforts are seconded by an enlightened new commission he will repeat the sanitary triumph of Havana, and we shall see another tropical pesthole converted into a health resort through the application of the discoveries of modern science. Then the work of excavation can proceed merrily, and Sir Patrick Manson's fears of the invasion of Asia and the coast of California by yellow fever from the Isthmus will be allayed.

## THE COUNTRY DOCTOR AND THE SURGEON.

THE practitioner of medicine in the country is usually a busy man, too busy, as a rule, to find much time to devote to a consideration of his trials or to compare his condition with that of his supposedly more fortunate city brother. Whenever, therefore, he does break silence and essays to present his own ideas as to the mutual relations of city and country doctors, his views are almost always of interest.

In a recent issue of the *Medical News,* Dr. B. R.

Riley takes up the subject of specialism and declares that its present tendency is to make the general practitioner in the country, a weak man, at least in a surgical way. He is a fair diagnostician and a good all-around man, and he approaches his case on all sides except the surgical one. This he turns over to the superior ability of his city confrère, and no small amount of the knowledge acquired by the latter, has been derived from cases sent him by the country practitioner. According to the author, the country practitioner who gives no thought to surgery, other than to bemoan his inability to practise it under the conditions which surround him, and accordingly sends his patients to the city, is the rule, not the exception. But he hopes for a better day when the country practitioner will no longer act as the shipping clerk to his haughty city colleague. There is no reason why this should be, for the country doctor is often, if he but knew it, the superior of his urban brother. The former will reduce a dislocation or treat a fracture, and seldom, if ever, loses a great deal of sleep over the worst cases, but "the city surgeon will approach a dislocation or a fracture with the one thought that it is a walking advertisement of either inferior or average ability, and actually loses more sleep over a simple fracture than over an abdominal section. Thus the country practitioner assumes easily the burden of responsibility that seems to rest heavy on the city surgeon. Why? The public is accustomed to having fractures reduced at home. If he accepts the responsibility and takes the chances that bring little money or prestige, and may bring criticism and damage suits, why not attempt operations that bring money and fame with less chance of disgrace?" In spite of the lack of favoring surroundings which often attend surgical cases in the country, Dr. Riley maintains that the country doctor can make his hands as surgically clean, and the home as sterile as is the case in the city hospital. If capable, he can, with impunity, attempt the same work with the same assurances of success that the city man has. With reference to the specialties, it may be necessary to send certain cases to the city, but with reference to surgery, it lies with him to say whether he shall send all his patients needing major operations to the city or not. He must hold before him only one thought, that of competency. Conservatism must not take the place of common sense. "Conservative surgery is all right, but the country practitioner is too prone to neglect or omit and call it conservatism, when in reality it is as much a malpractice act to neglect as it is to do wrong in the first place." Under present circumstances, surgery in the country is becoming one of the lost arts, and the writer's remedy for this state of things is for the man in the country to go to the city every two or three years, and attend on post-graduate courses and hospital clinics.

The country practitioner has always been noted for his self-reliance, and this paper shows that he is beginning soberly to consider some of his drawbacks and is hitting on the right means for their removal. Throughout the well-settled portions of the country, very few practitioners are outside of the range of some well-ordered hospital. It may be located in a very small city, but at the present time many communities are amply supplied in this respect, and the effect of hospital establishment in these communities has done much for surgical science in all the regions roundabout.

### High Irrigation of the Intestine.

In the *Berliner klinische Wochenschrift* of August 21, 1905, Aldor again calls attention to the local treatment of the intestine by means of high irrigations. This procedure, the value of which he thinks cannot be overestimated, has lost a great deal of its popularity in late years, because of the insistence by many investigators that the measure was based upon an erroneous conception. They held that not only no fluid could pass to the ileocecal valve, as the advocates of this form of medication claimed, but that the tube through which the fluid was to be injected itself remained in the sigmoid flexure, either pushing the wall of this portion of the intestine toward the opposite side of the abdomen, or, if the length of the mesentery prevented, rolling up upon itself in the lumen of the sigmoid. The result would be an accumulation of the injected fluid in the lower part of the large intestine, and in the inability of the patient to retain the injected fluid these investigators found the clinical proof of their hypothesis. As the result of five years of experience, Aldor, however, comes to other conclusions, substantiating, by means of the Röntgen pictures of the tube *in situ* his claim that, properly inserted, no obstacle to the passage of a soft rubber tube into the colon normally exists. The numerous observations made upon cadavers apparently reinforce the view of Aldor's opponents, but to this the writer opposes the fact that the conditions in the cadaver are quite dissimilar to those in the living subject in whom the peristalsis of the intestine affords valuable assistance in the introduction of the tube. The technique of the procedure is simple. The patient is placed upon his left side, and a soft rubber tube of sufficient length is introduced to a distance of about 40 cm., when it may be presumed to have passed the sigmoid flexure. By digital examination the course of the tube may be followed far enough to determine whether it has become coiled upon itself, while another indication that it has not caught in a fold of the mucosa is afforded by the direction in which it advances. Should further control be necessary, the tube may be withdrawn; if it has been coiled up in the sigmoid, the soft rubber will still bear the marks of the twists upon it. Boas has asserted that low irrigations are in themselves sufficient to reach the ileocecal valve, basing his statement upon the observation that in a patient in whom a cecal fistula had been established, the fluid from such an irrigation escaped through the colostomy wound. This, however, is an abnormal condition, and no conclusions can be drawn therefrom. Not alone does Aldor's method, the author of it claims, prevent the tenesmus arising from an accumulation of fluid in the rectum, it makes possible the treatment of the mucosa of the large intestine without surgical interference, thus obviating the insult to the appendix involved in the newly conceived operation of appendicostomy.

### The Danger of Too Much Zeal.

It is a well authenticated fact that chronic ulcerations may, under the influence of long-continued irritation, become converted into typical carcinomatous processes. A leucoplakia of the oral mucous membrane differs from the ordinary type of ulceration, still it is the outward expression of a chronic irritation commonly due to syphilis or tobacco, and also

offers a fertile soil for the development of a cancer. As a general thing, its presence signifies a grave prognosis, and many remedies have been proposed for its eradication. Of these only two have been attended with any degree of success, viz., the use of the actual cautery and excision of the patches with suture of the wound margins. Among the unfavorable results which may attend these procedures is the possibility that they themselves may give rise to the development of a particularly severe form of malignant disease. This is illustrated in a case reported by Kolaczek (*Deutsche Aerzte Zeitung*, June 1, 1905). The patent, a man of 48, gave a history of syphilis early in life, and was also an inveterate smoker, so that the cause for an extensive leucoplakia was not far to seek. As the patches gave considerable annoyance, their removal was decided upon, the larger ones being excised and the smaller ones destroyed with the thermocautery. At the site of one of the latter, on the upper lip, there soon developed an indurated ulcer, and four weeks later an enlargement of the submaxiliary lymph-nodes, the picture presenting every evidence of malignancy. Excision of the growth with the glands was followed by healing, although within three months the anterior chain of cervical lymph-nodes became enlarged and were removed. Two and a half years later the patient again presented himself with an extensive recurrence involving all the glands down to the clavicle. Operation failed to do any good, and the patient developed a cachexia to which he quickly succumbed. Kolaczek believes that the operative interference was the factor which brought about the malignant change in an already predisposed field, the severe reaction which attended the cauterization inducing a backward migration of the offending cells into the lymph channels. The suggestion advanced by this writer will probably account for the rapid new growth which often takes place where a cancerous tumor has been operated upon. The lesson to be gained from the recital of this case is, that any procedure which induces a severe reaction, such as might follow the use of the cautery, should be avoided in the treatment of leucoplakia and other suspicious lesions of a similar character. Simple excision would seem to meet better the required conditions. Another thought suggested by this case is that there is possibly such a thing as meddlesome surgery. The advice given not long since by one of the leaders of American surgery to remove all moles and other excrescences which may, or may not, some day undergo malignant change, while in principle eminently sound, may sometimes be followed too literally for the good of the patient.

### The Value of a Little Greek.

An esteemed British contemporary some time ago resented a comment of our London correspondent, who said, anent the desirability of the retention in the university curriculum of a little Greek: "Even that little, *pace* the Dons, might have prevented the appearance in one of our medical journals during the last month of three communications on 'afebrile' enteric fever." Whereupon our criticised contemporary remarked somewhat warmly: "A pedant, without any knowledge of medicine, might conceivably find fault with an expression which he would probably consider—quite mistakenly—to be a 'bull.' But to the physician, who thinks more of things than of words, 'afebrile enteric fever' is as legitimate a phrase as, for example, 'apyretic pneumonia.' In any case, in the name of etymological common sense, what has Greek to do with *febris?* We are inclined to think that our critic's zeal for Greek, like that of not a few of its defenders, is purely altruistic." All of which is delightful, because such unconscious testimony to the justness of our correspondent's observation. "Sam," said the quizzical darkey, "yo' ben trabelin' in de Orient, hab yo'? Well, how'd yo' like Turkey?" "Turkey?" said the other. "W'y stuffed wif ches'nuts an' oystahs—er—er——" "G'wan, yo' fool niggah! What's turkey got ter do wif trabelin' in de Orient, anyhow—huh?"

### Long Lived Doctors.

In the comparat've mortality tables physicians do not take a high place, coming after clergymen, gardeners, teachers, artists, lawyers, and those following many industrial pursuits, and themselves preceding in general only those engaged in admittedly hazardous occupations. But though the average of life in members of the medical profession is below the normal, individuaal instances of longevity among physicians are not uncommon. This is strikingly shown in the obituary notes in another column of this issue. Among the ten deaths reported by our correspondents in various parts of the country there were five of physicians eighty years old or older, and only two of those below seventy two years. The average age at death of the first five was 85.2 and that of the ten was 74.5 years. The oldest on the list died at the ripe age of ninety-six years.

## News of the Week.

**The Harvey Society Lectures.**—The first lecture of the recently organized Harvey Society will be given by Professor Hans Meyer, the distinguished pharmacologist of the University of Vienna. Professor Meyer will speak in German upon the subject "Die Theorie der Narcose." The lecture will be held on Saturday, October 7, at 8.30 P. M., in the New York Academy of Medicine. The second lecture will be given on October 14, at the same hour and place, by Professor Carl von Noorden, of Frankfort, the well-known authority on diabetes. The title of Professor von Noorden's lecture is "Modern Problems of Metabolism." The lecture will be delivered in English. Other lectures of the course will be given by Professors L. F. Barker, Howell, Lee, Levene, Mendel, Minot, T. H. Morgan, Novy, Park, Theobald Smith, and J. C. Webster. It is hoped by the founders of the Harvey Society that it may be of use in furthering the wider diffusion of knowledge of the medical sciences. The Harvey Society cordially invites those interested to attend these lectures.

**Needs of the Chicago Health Department.**—Health Commissioner Whalen has made the statement that meat inspection in Chicago is inadequate, and says that where six inspectors are now at work, forty are needed. It is impossible for a few inspectors to prevent the sale of meat which has become unwholesome after its inspection at the yards when it is distributed over the immense area of Chicago by hundreds of obscure retail dealers. Dr. Whalen also says that the staff of sanitary inspectors should be increased, and he believes Chicago could not expend money more usefully than in the development of an efficient, well equipped, and non-political body of inspectors and a scientific and comprehensive system of food and sanitary inspection.

**Alcoholic Patent Medicines.**—Under a decision rendered by the Commissioner of Internal Revenue every druggist who after December 1 of this year may sell certain so-called patent medicines having whiskey or other distilled spirits as the chief ingredient will be obliged to pay a special tax to the Government as a liquor dealer. The manufacturers of these medicines will be required to pay the special tax imposed upon rectifiers and liquor dealers. Some of the worthy members of the W. C. T. U. will be surprised when they learn that their favorite nerve tonic and all-around bracer is nothing but whiskey, and bad whiskey at that.

**Virginia's Tax on Physicians.**—The Medical Society of Virginia is engaged in an effort to have repealed the law which imposes a special license tax of from ten to twenty-five dollars a year on physicians. Under the direction of the society there is being published a paper, *The Medical Legislator*, which has taken up the cudgels in behalf of the move. The paper is edited by Dr J. Beverley Deshazo of Ridgeway.

**War Against Contract Practice.**—At the annual meeting of the New Hampshire State Medical Association, held last April, a resolution was passed to the effect that no physician doing contract practice for fraternal organizations after January 1, next, would be permitted to remain a member of the society. This action was endorsed last week by the Manchester Medical Society and the Nashua Medical Society, and it is believed that all the county and local societies throughout the State will take similar action. The Peterborough (Ontario) Medical Society recently discussed the same question at a meeting held September 7 to act upon a resolution introduced some time ago, forbidding lodge, factory, and other contract medical practice after January 1, 1906. The committee appointed to canvass the local profession reported that there was no approach to unanimity and recommended that no action be taken. The matter was therefore dropped for the present.

**Law Regarding Embalming.**—The Illinois State Board of Health, through its Secretary, Dr. James A. Egan, has issued the following notice to Illinois embalmers: "Under the provisions of the Act approved May 13, 1905, no person shall embalm or prepare for transportation any body dead of a contagious or infectious disease or embalm any dead body, or hold himself out as practising the art of embalming, unless he holds a license from the State Board of Health authorizing him so to do. After September 1 1905, no transportation company operating in the State of Illinois will accept a body dead of any contagious or infectious disease, unless it has been prepared by an embalmer holding a license issued by the State Board of Health. After January 1, 1906, any person who shall embalm or prepare for transportation any body dead of a contagious or infectious disease, or embalm any body, or hold himself out as practising the art of embalming without having obtained a license from the State Board of Health, shall be deemed guilty of a misdemeanor."

**Treatment of the Morally Insane.**—In a special despatch to *The Sun* from Berlin, dated September 16, it is stated that Professor Liszt of Berlin in a paper on "moral insanity," which was read at the Congress of Criminologists, submitted that special measures must be carried out to render morally insane persons, whether criminals or not, harmless to society. Secondly, the professor insisted that morally insane persons must be punished with less severity than others. Professor Torp of Copenhagen opposed the second proposition. He said it was customary in Denmark to punish the morally insane less severely than ordinary criminals, but the system provoked general discontent. It was only suitable for those who were irresponsible from external causes such as drunkenness. Experience showed that persons who were morally insane were not susceptible to improvement by punishment, and always relapsed into crime. They should not be punished but should be dealt with by special treatment. Dr. Kielhorn, representing the schools of Hamburg, said the percentage of morally insane children was far greater than was generally believed. Over 1,000 were taught in nine Hamburg schools. Two per cent. were confirmed criminals, whose rescue was hopeless, but the remainder could be reformed by suitable treatment. Punishment by imprisonment or detention did more harm than good. After a long debate, in which many speakers denounced Prof. Lizst's propositions as unworthy compromises, both were adopted by a large majority.

**The "Denver Medical Times."**—Dr. Thomas H. Hawkins has retired form the active management of this journal, though he continues on the editorial staff. A stock company has been formed to publish the paper. The commercial side of the journal will be directed very properly by business men, though all the editors are personally interested in the success of the publication, being stockholders in the owning company.

**Society Meetings in New York.**—Two national medical societies—the American Association of Obstetricians and Gynecologists and the American Electro-Therapeutic Association—have held their annual meetings in New York this week, the first named at the Hotel Astor and the second at the Academy of Medicine.

**Cholera.**—The German sanitary authorities appear to be gaining the upper hand of the cholera invasion. For the twenty-four hours ending at noon September 19 there were but seven new cases reported, and no deaths, the totals from the beginning of the outbreak being 208 cases and 75 deaths.

**Yellow Fever in Cincinnati.**—A trainload of refugees from Louisiana bound for Cincinnati last week were met by Dr. B. F. Lyle at Lexington, Ky., and on their arrival five suspects were sent to the Branch Hospital, where they were found later to be suffering from yellow fever.

**Cook County Hospital Staff.**—Examinations for candidates for positions on this staff will begin on September 28. The successful candidates will be placed on the civil service eligible list, and when vacancies occur on the staff they will be assigned to fill them. The life of the present staff cannot exceed six years, as fixed by the civil service act passed by the Illinois Legislature, and no member of the present staff will be permitted to serve a second term. The County Civil Service Commission will hold the examination but the examining board of reputable physicians, and surgeons will have charge of its chief details.

**War on Unclean Dairies.**—The Board of Health of East St. Louis, Ill., has inspected all the dairies in that city, and declared a number of them unsanitary and ordered them closed. The owners have been given thirty days in which to put their places in a sanitary condition, when they will be passed upon, and if found satisfactory will be permitted to resume business. Other owners were warned of unsanitary conditions prevailing in and around their dairies and were instructed to clean up their places at once.

**Medical Ethics in the College Curriculum.**—The Philadelphia County Medical Society has adopted a resolution requesting all medical schools to furnish their senior class with a special course of lectures or addresses upon the subjects of Medical Ethics and the Business Aspect of the Practice of Medicine, and including the recommendation that graduates promptly join the local county medical society.

**Decrease in Typhoid Fever in Chicago.**—Chicago, twelve years ago, had the highest death rate from typhoid fever of any large city in the world (17.22 in the ten thousand of population in 1891 and 12.21 in 1892), but last year the rate was only 1.92 per ten thousand—among the lowest of all large cities.

**The School of Medicine of Purdue University.**—On September 1, 1905, by the unanimous action of their respective Boards of Trustees the Medical College of Indiana was made the Medical Department of Purdue University with the title of "Indiana Medical College School of Medicine of Purdue University." The Medical College of Indiana was founded in October, 1869, and has given continuous instruction in Indianapolis for thirty-five years, graduating in that time over 1600 students

**Laying of the Corner-stone of Washington Park Hospital, Chicago.**—The corner-stone of this hospital was laid September 4. The building will be three stories high, 145 by 44 feet, and will have a capacity of 75 beds. The cost is to be $50,000. It will be ready for occupancy January next and will have a total capacity of 105 beds

**Decrease in Death Rate From Consumption at the Dunning Institutions, Illinois.**—The mortality rate from this disease in these institutions has decreased 15.31 per cent. since patients have been removed to the new tuberculosis hospital. This is said to be due to the surroundings at the new hospital. In the months of March, April, May, June, July, and August of last year, the death rate of tuberculous patients was 42.52 per cent., while during the corresponding months this year the mortality rate has been 27.21 per cent.

**The Germ of Yellow Fever.**—It is again reported from New Orleans that the Drs. Archinard have discovered the microorganism of yellow fever, and that a definite and authoritative announcement of this will soon be made.

**Prickly Heat in New Orleans**—The residents of New Orleans have been suffering in a remarkable and unusual degree from prickly heat, an affection which, despite the prolonged summer is not very common there. It has been found that most of the sufferers had been experimenting with the arsenization method of preventing yellow fever, which consists in taking arsenic in small amounts daily for a long period of time, and many have attributed their discomfort to that fact.

**Sickness in the Russian Army.**—A despatch from St. Petersburg says that the Council of Defense of the empire, under the presidency of the Grand Duke Nicholas Nicholaevitch has announced that the mortality in the Russian army is twice as great as the mortality among the population of the country. After service in the field twelve per cent. of the soldiers become invalids and twenty-two out of every thousand become tuberculous

**The Southern Medica Training School,** a college for the education of medical missionaries, has been opened in Atlanta. The institution, which is coeducational, is empowered by its charter to confer the degree of M.D. on those who have complied with the legal requirements The dean of the faculty is Dr. J. McFadden Gaston.

**Teetotalism in the Canal Zone.**—A convention of prohibitionists in Massachusetts have adopted a resolution calling for the interdiction of the sale or the gift of alcoholic liquors on the Canal Zone to any employee of the government. The penalty which they wish imposed for infraction of this law is thirty days' imprisonment and expulsion from the Canal Zone. A copy of the resolution has been sent to the President.

**An Epidemic of Typhoid Fever** exists at Nanticoke Pa., where there were 205 cases on September 14. The borough building has been turned into a hospital and the hospitals of Wilksbarre, Scranton, and Hazleton have arranged to take some of the patients. A large number of experienced nurses have been engaged, and every householder has received orders to boil all water and milk used.

**The Crusade Against Mosquitos**—A thorough discussion of ways to exterminate the mosquito will take place at the second Pan-American Sanitary Convention to meet in Washington on October 9. All South American republics will be represented and many European scientists will attend. The program gives a large place to papers on yellow fever, the plague, cholera, and malaria Each South American republic will report on the sanitary conditions in its territory.

**The Houghton County (Mich.) Medical Society** held its annual meeting at Hancock on September 4. Officers for the ensuing year were elected as follows: *President*, Dr. N. S. MacDonald, *Vice-President*, Dr. C H. Rodi, *Secretary and Treasurer*, Dr S. S. Lee, *Board of Censors* for three and two years respectively, Drs. E. T. Abrams and W K. West

**Dr John Williams** has been appointed by the Ontario government medical superintendent of the provincial epileptic hospital at Woodstock. He is a graduate of the medical Department of the University of Toronto in 1873.

**Three Chinese Surgeons** recently arrived in San Francisco on their way to attend the meeting of the Association of Military Surgeons at Detroit next week. They are Dr Ho Kan Yuen of the navy, Dr Ying Young Tsui of the army, and Dr. Wang Pang Chung of the South China army. All of them have been educated in England or the United States.

**The Erie Railroad Surgeons' Association** held its annual meeting in this city on September 13 and 14. The following officers were elected. *President*, Dr. M. S. Cramer of Ohio City, O.; *Vice-President*, Dr. D. A. Currie of Englewood, N. J.; *Secretary*, Dr J. A. Allis of Upper Montclair, N. J.

**The Washington County (Vt.) Medical Association** held its fourth annual meeting at Barre on September 12. The following officers were elected: *President*, Dr. William Lindsay of Montpelier; *Vice-president*, Dr. C. F. Camp of Barre; *Secretary*, Dr. O. G. Stickney of Barre, *Treasurer*, Dr. C. E. Chandler of Montpelier; *Censors*, Dr. F. W. Burbank of Cabot and W. F. Lazelle of Barre.

**Appointment of Asylum Superintendents in ontario.**—The Government has made the following changes in the superintendency of the provincial hospitals for the insane: Dr. C. Clark of Rockwood Asylum to be superintendent of the Toronto Asylum, vice Dr. Daniel Clark, retired. Dr. E.

E Ryan of the Kingston Asylum to be medical superintendent of the Rockwood Asylum. Dr. E. C. McKay of Morrisburg to be medical superintendent at Cobourg Asylum, vice Dr. E. McNeil.

**Call for a Southern Quarantine Convention.**—A formal call was issued on September 16 for a Southern conference on quarantine and immigration to be held in Chattanooga on November 9 and 10. It is signed by twelve Governors and the officers of the Chambers of Commerce of several cities An object of the meeting is to obtain "some uniform system of quarantine that will allay apprehensions of the people and minimize the dangers resulting from an outbreak of yellow fever." The call declares: "This is necessary if we would save our land from the demoralizing and brutalizing tendencies of a panic-inspired quarantine." The call was signed by the Governors of Tennessee, Louisiana, Maryland, West Virignia, Virginia, Florida, Mississippi, Missouri, Kentucky, South Carolina, Texas, and Georgia.

**Obituary Notes.**—Dr. Asa S. Allen died in Cleveland on September 6, at the age of ninety-six years. He was born in Martha's Vineyard and went to Cleveland in 1842. He practised medicine for many years in Akron and Berea, Ohio, but retired about fifteen years ago.

Dr. Ephraim J. McCollum died in Tiffin, Ohio, on September 7, at the age of eighty-five years. He was a graduate of the Jefferson Medical College in the class of 1853. The physicians of Seneca County united two years ago in the celebration of his golden jubilee of practice.

Dr. C. G. Royster died at Trenton, Ky., on September 4, at the age of eighty-three years. He was graduated in medicine in Philadelphia in the early 40's, and after practising for a time in Montgomery County moved to Paducah. He retired many years ago on account of feeble health and advancing years.

Dr. Thomas Menees of Nashville died September 6 in his eighty-third year. He was born in Davidson County, Tenn., June 26, 1823 and was graduated from the Medical Department of Transylvania University in 1846. He began practice in Springfield, and later removed to Nashville. He always took an active interest in public affairs and was State Senator for one term and was a Representative in the Confederate Congress from 1861 to the dissolution of that government. In 1873 Dr. Menees was elected Professor of Materia Medica and Therapeutics in the University of Nashville. In the following year he was elected Professor of Obstetrics in the University of Nashville and Vanderbilt University. After the separation of the medical departments of the two universities he accepted a chair in Vanderbilt University. His three sons became physicians, but none of them is living; one lost his life in Memphis during the yellow fever epidemic in 1878. He leaves a grandson, a practitioner. Dr. Menees continued in fairly active practice until about a year ago.
